(Received 2 March 2009; published 21 May 2009)

Experiment E949 at Brookhaven National Laboratory has observed three new events consistent with the decay  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  in the pion momentum region  $140 < P_\pi < 199$  MeV/c in an exposure of  $1.71 \times 10^{12}$  stopped kaons with an estimated total background of  $0.93 \pm 0.17(\text{stat})_{-0.24}^{+0.32}(\text{syst})$  events. This brings the total number of observed  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  events to seven. Combining this observation with previous results, assuming the pion spectrum predicted by the standard model, results in a branching ratio of  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) = (1.73_{-1.05}^{+1.15}) \times 10^{-10}$ . An interpretation of the results for alternative models of the decay  $K^+ \rightarrow \pi^+ + \text{nothing}$  is also presented.

**I. INTRODUCTION**

This article is a detailed report of the final results from experiment E949 at Brookhaven National Laboratory on the study of  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  in the pion momentum region  $140 < P_\pi < 199$  MeV/c [1]. The observation of  $K^+ \rightarrow$

$\pi^+ + \text{nothing}$ , a charged kaon decay to a single charged pion and no other observable particles, is evaluated within the framework of the standard model (SM) and in terms of alternative models.

**A. Interpretation of the decay  $K^+ \rightarrow \pi^+ + \text{nothing}$** 

The only significant SM contribution to the experimental signature  $K^+ \rightarrow \pi^+ + \text{nothing}$ , where *nothing* represents experimentally unobservable particles, is  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  where  $\nu \bar{\nu}$  is  $\nu_e \bar{\nu}_e$ ,  $\nu_\mu \bar{\nu}_\mu$ , or  $\nu_\tau \bar{\nu}_\tau$  as discussed in Ref. [2]. The calculation of the branching ratio has undergone continual theoretical refinement and experimental narrowing of the relevant input parameters since the first modern treatment of this process [3,4]. A recent

assessment of the prediction for the branching ratio of this process is  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) = (0.85 \pm 0.07) \times 10^{-10}$  [5] where the quoted uncertainty is dominated by the uncertainty in the Cabibbo-Kobayashi-Maskawa quark-mixing matrix elements. This assessment included new small corrections to the charm quark contributions to the SM branching ratio.

There have been many alternatives to the SM interpretation of the  $K^+ \rightarrow \pi^+ + \text{nothing}$  signature suggested over the years, including the following:

- (1) New physical mechanisms contributing to  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  with the usual neutrino-antineutrino pairs. Many models incorporating new physics would result in a deviation from the SM prediction for  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$ . A summary of these through mid-2007 can be found in [6]. Since that time there have been new calculations of the branching ratio in the littlest Higgs model with  $T$  parity [7,8], the possible effects on the branching ratio of a heavy singlet up-quark [9], and a reassessment of the constraints of the minimal flavor violation model [10].
- (2) Cases in which the neutrino flavor is not conserved. There are examples stemming from extended technicolor [11], supersymmetry (SUSY) [12], and new effective four-fermion interactions involving neutrinos [13]. Like most examples of lepton flavor violation in kaon decay, these tend to be small, but there are cases such as some types of  $R$ -violating SUSY [14], in which  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  gives the limiting constraint on some of the couplings.
- (3) Reactions in which a single unseen particle recoils against the  $\pi^+$ . These include species of axions [15], the familon [16], sgoldstinos [17], a gauge boson corresponding to a new  $U(1)'$  group [18,19], and various light dark-matter candidates [20–22]. In general these models do not predict branching ratios; rather they use  $K^+ \rightarrow \pi^+ + \text{nothing}$  results to constrain parameters.
- (4) Other exotic processes. These include the effects of “unparticles,” which can change the SM  $\pi^+$  energy spectrum as well as the branching ratio [23].

## B. Previous results on $K^+ \rightarrow \pi^+ \nu \bar{\nu}$ below the $K_{\pi 2}$ peak

A detailed discussion of the history of measurements of  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  was given in [2]. However, most of these measurements were made in the kinematic region in which the  $\pi^+$  is more energetic than the  $\pi^+$  from the background reaction  $K^+ \rightarrow \pi^+ \pi^0$  ( $K_{\pi 2}$ ), dubbed the “ $\pi \nu \bar{\nu}(1)$ ” region. By contrast fewer measurements have been made in the “ $\pi \nu \bar{\nu}(2)$ ” region in which the  $\pi^+$  is less energetic than that from  $K_{\pi 2}$  (Fig. 1). As will be discussed below, this region is experimentally more challenging than the  $\pi \nu \bar{\nu}(1)$  region for a stopped-kaon geometry principally because the  $\pi^+$  from  $K_{\pi 2}$  decay can enter the  $\pi \nu \bar{\nu}(2)$  region if it undergoes a nuclear interaction in the stopping target.

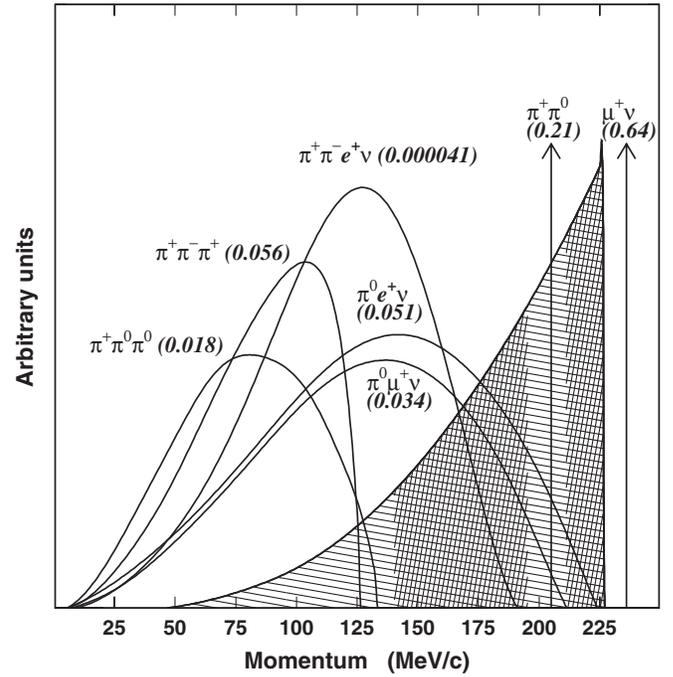

FIG. 1. Momentum spectra of charged particles from  $K^+$  decay in the rest frame. The values in parentheses represent the branching ratios of the decay modes [24]. The hatched spectrum represents the  $\pi^+$  spectrum from  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  decay assuming the  $V - A$  interaction. The densely hatched regions represent the  $\pi \nu \bar{\nu}(1)$  and  $\pi \nu \bar{\nu}(2)$  E949 signal regions.

Among the examples of  $\pi \nu \bar{\nu}(2)$  measurements was the first attempt to measure  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  in a heavy liquid bubble chamber experiment [25,26] at the Argonne Zero Gradient Synchrotron that was sensitive almost entirely to pion momenta below 200 MeV/c. This experiment achieved a 90% confidence level (C.L.) limit on the branching ratio of  $5.7 \times 10^{-5}$ , assuming a pure vector spectrum for the  $\pi^+$ . Limits of  $3.1 \times 10^{-5}$  and  $2.3 \times 10^{-5}$  were extracted under the assumptions of tensor and scalar interactions, respectively.

Some features of the bubble chamber experiment are notable. The experiment relied on the positive  $\pi^+$  identification by observation of the  $\pi \rightarrow \mu \rightarrow e$  decay chain ( $\pi^+ \rightarrow \mu^+ \nu$  followed by  $\mu^+ \rightarrow e^+ \nu_e \bar{\nu}_\mu$ ). Although no timing information was available, kinematic information (specifically the measured range of the  $\pi^+$  and the angle between the incoming  $K^+$  and outgoing  $\pi^+$ ) was used to reject background due to  $K^+$  decay in flight. Events were discarded that showed evidence of a  $\pi^+$ -nucleus interaction in the form of a drastic change in ionization along the  $\pi^+$  track or a kink in the  $\pi^+$  trajectory. Photon detection with a stated inefficiency of 0.02 was used to veto  $\pi^0$  decay products and provided additional background suppression.

There followed a series of scintillation counter experiments by a Chicago-Berkeley group that included a measurement in the range  $142.7 \text{ MeV}/c < P_{\pi^+} < 200.9 \text{ MeV}/c$

[27]. This yielded a 90% C.L. upper limit on the branching ratio of  $9.4 \times 10^{-7}$  assuming a vector spectrum. Corresponding limits were also determined assuming a tensor spectrum,  $7.7 \times 10^{-7}$ , a scalar spectrum,  $1.1 \times 10^{-6}$ , and other possible shapes. In contrast to the bubble chamber experiment, the counter experiment made use of a delayed coincidence of 3.3 ns between the stopped  $K^+$  and the outgoing track to suppress beam-related background including  $K^+$  decay in flight. A hermetic  $4\text{-}\pi$  sr photon detector  $\sim 10$  radiation lengths (r.l.) thick (4.3 r.l. along the incoming beam channel) achieved a measured inefficiency for  $\pi^0$  detection of  $< 2.2 \times 10^{-5}$  at 90% C.L. for identified  $K_{\pi 2}$  decays [28]. As with the bubble chamber experiment, the  $\pi \rightarrow \mu \rightarrow e$  chain was used for positive  $\pi^+$  identification and the measured range of the  $\pi^+$  provided the kinematic information used in the analysis. A subsequent experiment at KEK that probed the  $\pi \nu \bar{\nu}(1)$  region improved the detection and identification of the  $\pi \rightarrow \mu \rightarrow e$  decay by using 500 MHz waveform digitizers [29].

The next attempt at a measurement in the  $\pi \nu \bar{\nu}(2)$  momentum region emerged out of the first phase of the E787 experiment at Brookhaven National Laboratory [30]. The E787 detector utilized and built upon concepts from the earlier experiments. This experiment obtained a 90% C.L. upper limit of  $1.7 \times 10^{-8}$ , assuming a  $V - A$  spectrum modified by a form factor obtained from  $K^+ \rightarrow \pi^0 e^+ \nu$  data [31]. We henceforth refer to this form as the ‘‘standard model’’ interaction. E787 also obtained limits of  $1.4 \times 10^{-8}$  and  $2.2 \times 10^{-8}$ , respectively, assuming pure tensor and scalar interactions using  $\pi \nu \bar{\nu}(2)$  data exclusively [32]. Adding  $\pi \nu \bar{\nu}(1)$  data, E787 improved the limits to  $1.0 \times 10^{-8}$  and  $1.8 \times 10^{-8}$ , respectively [33].

The second generation of this experiment improved the SM limit in the  $\pi \nu \bar{\nu}(2)$  region to  $4.2 \times 10^{-9}$  [34] and subsequently to  $2.2 \times 10^{-9}$  [35]. Assuming tensor and scalar interactions E787 ultimately obtained limits of  $1.8 \times 10^{-9}$  and  $2.7 \times 10^{-9}$ , respectively [36].

## II. THE E949 DETECTOR

### A. Detector description

The E787 detector was upgraded in 1999–2000 to create the successor experiment E949 [37]. An extensive and detailed description of experiment E949 has been provided elsewhere [2]. In this section we provide a summary description of the detector and emphasize the features essential to the  $\pi \nu \bar{\nu}(2)$  region.

E949 used an incident 710 MeV/c  $K^+$  beam that was slowed and stopped in the scintillating fiber target as shown schematically in Fig. 2. Observation of the decay  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  requires detection of the incoming  $K^+$  and outgoing  $\pi^+$  in the absence of any other coincident activity. The charged pion was identified kinematically by kinetic energy ( $E_\pi$ ), momentum ( $P_\pi$ ), and range ( $R_\pi$ ) measurements and by observation of the  $\pi \rightarrow \mu \rightarrow e$  decay sequence. Since the  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  branching ratio was expected to be

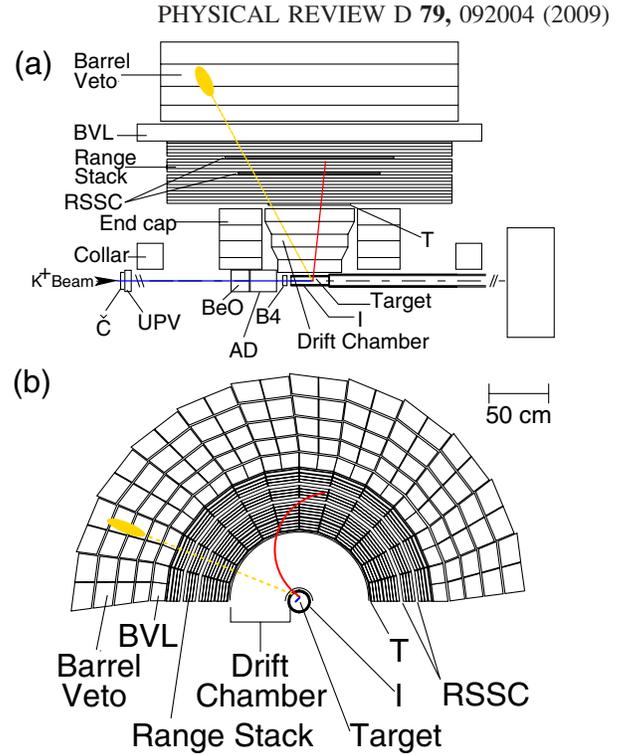

FIG. 2 (color online). Schematic side (a) and end (b) views of the upper half of the E949 detector. An incoming  $K^+$  is shown traversing the beam instrumentation, stopping in the target and decaying to  $\pi^+ \pi^0$ . The outgoing charged pion and one photon from the  $\pi^0 \rightarrow \gamma \gamma$  decay are illustrated. Elements of the detector are described in the text.

at the  $10^{-10}$  level, the detector was designed to have powerful  $\pi^+$  identification to reject backgrounds from  $K^+ \rightarrow \mu^+ \nu_\mu$  ( $K_{\mu 2}$ ),  $K^+ \rightarrow \mu^+ \nu_\mu \gamma$  ( $K_{\mu 2 \gamma}$ ), and  $K^+ \rightarrow \mu^+ \pi^0 \nu_\mu$  ( $K_{\mu 3}$ ), photon detection coverage over the  $4\text{-}\pi$  solid angle to reject  $K_{\pi 2}$  and  $K^+ \rightarrow \pi^+ \pi^0 \gamma$  ( $K_{\pi 2 \gamma}$ ), and efficient identification of a single incoming  $K^+$  to suppress beam-related background.

The incoming charged-particle beam, containing approximately three  $K^+$  for every  $\pi^+$ , traversed a Čerenkov counter, two stations of beam wire proportional chambers (BWPCs), a passive BeO degrader, an active degrader (AD), and a beam hodoscope (B4) as shown in Fig. 2. The BWPCs, located between the upstream photon veto (UPV) and BeO, are not explicitly shown in the figure. Typically,  $1.6 \times 10^6$  kaons/s entered the target during a 2.2 s spill. Čerenkov photons emitted by an incoming  $K^+$  ( $\pi^+$ ) passing through a lucite radiator were transmitted (internally reflected) into 14 ‘‘kaon’’ (‘‘pion’’) photomultiplier tubes to form  $C_K$  ( $C_\pi$ ) coincidences. The photomultiplier tube (PMT) signals were split and fed to a discriminator and a  $\times 10$  amplifier. The discriminator output was used as input to the time-to-digital converters (TDCs) and to the trigger (Sec. II B). The amplifier outputs were fed to 500 MHz charge-coupled devices (CCDs) [38]. The first (second) BWPC station was located downstream

of the Čerenkov counter at 168.5 (68.5) cm from the target entrance and each contained three planes with sense wires in the vertical and  $\pm 45^\circ$  ( $\pm 60^\circ$ ) to the vertical direction. The wire spacing in the first (second) station was 1.27 (0.80) mm. The BWPCs enabled detection of multiple beam particles. The degraders were designed such that incident kaons stopped within the fiducial volume of the scintillating fiber target. The AD consisted of 40 layers of 2-mm thick plastic scintillator (13.9 cm diameter) interleaved with 39 disks of 2.2-mm thick copper (13.6 cm diameter). The scintillator was azimuthally divided into 12 sectors that were coupled by wavelength-shifting (WLS) fibers to PMTs that were read out by analog-to-digital converters (ADCs), TDCs and CCDs. These devices enabled measurement of activity in the AD coincident with the incoming beam and outgoing products of  $K^+$  decays. The B4 hodoscope downstream of the AD had two planes of 16 segmented plastic scintillator counters with 7.2-mm pitch oriented at  $\pm 33.5^\circ$  with respect to the horizontal direction. The cross section of each counter was in a “Z shape” to minimize the inactive area traversed by the beam and to improve the spatial resolution [39]. Each counter was connected to a PMT by three WLS fibers and each PMT was read out by an ADC, a TDC, and a CCD. The B4 enabled a measurement of the target entry position of the beam particle as well as identification of the incident particle by energy loss.

The target was composed of 413 scintillating fibers 3.1-m long with a 5-mm square cross section packed to form a 12-cm-diameter cylinder. A number of smaller (1-, 2-, and 3.5-mm square) “edge” fibers filled the gaps at the outer edge of the target. Each 5-mm fiber was connected to a PMT and the output PMT signal was split and input into an ADC, a TDC, and low-gain ( $\times 1$ ) and high-gain ( $\times 3$ ) CCDs. The target-fiber multiplicity and energy sum were also generated for triggering purposes. Multiple edge fibers were ganged onto 16 PMTs with similar readout. Analysis of the 500 MHz sampling information provided by the target CCDs was essential for isolating and suppressing backgrounds in the  $\pi\nu\bar{\nu}(2)$  region. Two cylindrical layers of six plastic-scintillation counters surrounding the target defined the fiducial volume. The inner layer of counters (dubbed “I counters” or “ICs”) were 6.4-mm thick with an inner radius of 6.0 cm and extended 24 cm from the upstream end of the target. The 5-mm thick outer scintillation counters (VC) overlapped the downstream end of the ICs by 6 mm and extended 196 cm farther downstream. The VC served to veto particles that exited the target downstream of the IC. Each IC and VC element was instrumented with a PMT and read out by an ADC, a TDC, and a 500 MHz transient digitizer (TD) [40].

The origin of the E949 coordinate system was the center of the cylindrical volume defined by the ICs. This point also coincided with the center of the drift chamber. E949 employed a right-handed Cartesian coordinate system with

$+z$  in the incident beam direction,  $+y$  vertically upward, and the polar angle  $\theta$  defined with respect to the  $+z$  axis. The entire spectrometer was surrounded by a 1 T solenoidal magnetic field in the  $+z$  direction.

The drift chamber, also called the “ultrathin chamber” (UTC) [41], was located just outside the IC, extended radially from 7.85 to 43.31 cm and served to measure the trajectory and momentum of the charged track from the target to the range stack as shown in Fig. 2. Each of the three superlayers of the UTC contained four layers of axial anode wires that provided  $xy$  position information and two cathode foil strips that provided  $z$  position information. Beginning at an inner radius of 45 cm, the range stack consisted of 19 layers of plastic scintillator counters and double-layer straw chambers (RSSC) [42] embedded after the 10th and 14th layers of scintillator. The range stack enabled the measurement of the range and energy of the charged particle, the observation of the  $\pi \rightarrow \mu \rightarrow e$  decay sequence, and the measurement of photon activity. The 19 layers of plastic scintillator counters were azimuthally segmented into 24 sectors as shown in Fig. 2. Layers 2–18 (19) were 1.9 (1.0)-cm thick and 182 cm long and were coupled on both ends to PMTs through lucite light guides. The trigger counters ( $T$  counters) in the innermost layer served to define the fiducial volume for  $K^+$  decay products and were 6.4-mm thick and 52-cm long counters coupled to PMTs on both ends by WLS fibers. The  $T$  counters were thinner than layers 2–19 to suppress rate due to photon conversions. Signals from each range stack PMT were passively split 1:2:2 for ADCs, discriminators, and fan-in modules. The discriminator outputs were sent to TDCs and used in the trigger. The fanned-in analog sum of four adjacent sectors (dubbed a range-stack “hexant”) was fed into a single TD and was provided to the trigger. The TDs digitized the charge in 2 ns intervals with an 8-bit resolution. The 500 MHz sampling permitted the observation of a  $\pi^+ \rightarrow \mu^+$  decay with a 5-ns separation between the stopped pion and the emitted muon.

Identification of  $K^+ \rightarrow \pi^+ \nu\bar{\nu}$  decays required detection of any activity coincident with the charged track. Photons from  $K_{\pi 2}$  and radiative kaon decays were detected in a hermetic photon veto system with  $4\text{-}\pi$  sr solid angle coverage as shown in Fig. 2. Except for the end caps (ECs), all photon veto detectors were lead-scintillator sandwich-style electromagnetic calorimeters. Other detector elements, such as the range stack, target, and AD, also served as photon veto detectors. The barrel veto (BV) and barrel veto liner (BVL) covered  $2/3$  of  $4\text{-}\pi$  sr outside the range stack with a radial thickness 14.3 and 2.29 r.l., respectively. The downstream and upstream ECs consisted of 13.5 r.l. thick undoped CsI crystals and covered approximately  $1/3$  of  $4\text{-}\pi$  sr [43,44]. The 3.1 r.l. thick upstream photon veto was mounted just downstream of the Čerenkov counter. The upstream and downstream collar (CO) counters shown in Fig. 2 provided approximately 4.5 and 9 r.l. at normal

incidence, respectively. An additional collar counter ( $\mu$ CO) was installed downstream of the downstream CO between the inner face of the magnet end plate and the target [2]. The downstream photon veto (DPV) provided 7.3 r.l. of coverage downstream of the target, EC, and collar. The AD was 6.1 r.l. thick and contributed important photon veto coverage in the poorly instrumented region near the beam axis. The thickness in radiation lengths of the photon veto system as a function of the cosine of the polar angle is shown in Fig. 3.

### B. Trigger

The trigger system for E949 was designed to select  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  events from the large number of  $K^+$  decays and scattered beam particles by requirements on the  $\pi^+$  range, evidence of a  $\pi^+ \rightarrow \mu^+ \nu \mu$  decay in the range stack, absence of other detector activity at the time of the  $\pi^+$ , and the presence of a preceding  $K^+$ . The elements and architecture of the two-stage trigger system have been described previously [2]; here we describe the features essential for the  $\pi \nu \bar{\nu}(2)$  region.

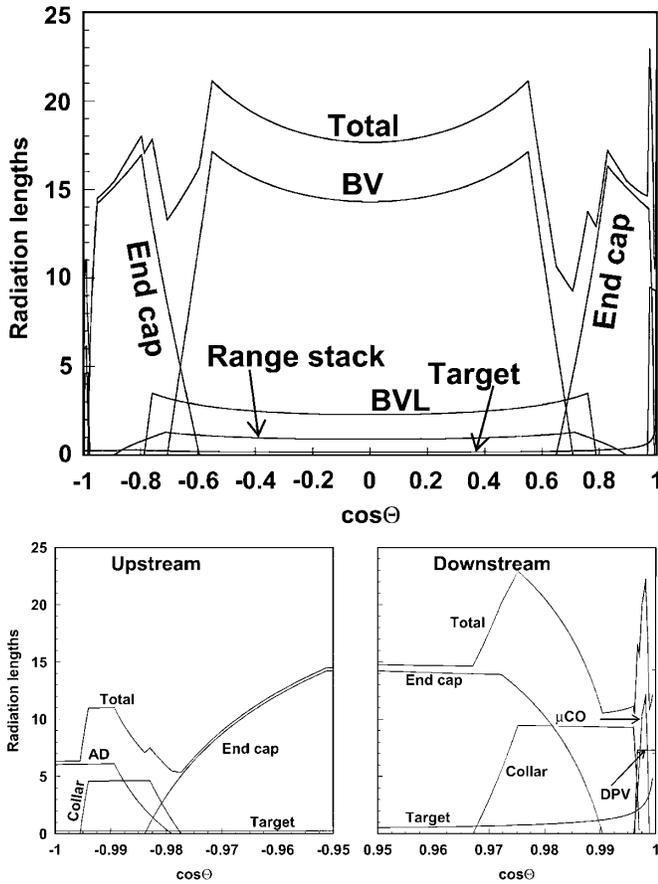

FIG. 3. (Upper panel) Contribution of each photon veto detector in radiation lengths as a function of  $\cos\theta$  for a photon emitted from the origin of the detector coordinate system. (Lower panel) Contribution of each photon veto element in the upstream and downstream regions within  $18^\circ$  of the beam.

The logical OR of the following two signal triggers was used for the  $\pi \nu \bar{\nu}(2)$  analysis:

$$\begin{aligned} \text{TRIG}\pi\nu\bar{\nu}(1) \equiv & KB \cdot (T \cdot 2 \cdot IC) \cdot DC \cdot (6_{\text{ct}} + 7_{\text{ct}}) \cdot \overline{19_{\text{ct}}} \\ & \cdot \overline{zfrf} \cdot L0rr1 \cdot HEX \\ & \cdot (BV + BVL + EC) \cdot L1.1 \cdot L1.2, \quad (1) \end{aligned}$$

$$\begin{aligned} \text{TRIG}\pi\nu\bar{\nu}(2) \equiv & KB \cdot (T \cdot 2 \cdot IC) \cdot DC \cdot 3_{\text{ct}} \cdot 4_{\text{ct}} \cdot 5_{\text{ct}} \cdot 6_{\text{ct}} \\ & \cdot (\overline{13_{\text{ct}} + \dots + 18_{\text{ct}}}) \cdot \overline{19_{\text{ct}}} \cdot L0rr2 \cdot HEX \\ & \cdot (BV + BVL + EC) \cdot L1.1 \cdot L1.2. \quad (2) \end{aligned}$$

We collectively refer to the OR of the  $\text{TRIG}\pi\nu\bar{\nu}(1)$  and  $\text{TRIG}\pi\nu\bar{\nu}(2)$  triggers as  $\pi\nu\bar{\nu}(1+2)$ .

The  $K^+$  beam condition  $KB$  required a coincidence of at least five  $C_K$  PMTs, the B4 hodoscope, and the target with at least 20 MeV of deposited energy. The  $KB$  signal served as the beam strobe for the trigger.  $T \cdot 2 \cdot IC$  required a coincidence of the first two range-stack layers in the same sector with at least one IC to ensure that a charged track exited the target and entered the range stack. The delayed coincidence ( $DC$ ) required the IC time to be at least 1.5 ns later than the  $C_K$  coincidence to select kaon decays at rest. The ‘‘ct’’ designation refers to the range stack  $T \cdot 2$  sector and the next two adjacent sectors that would be traversed by a positively charged particle in the magnetic field. For the  $\text{TRIG}\pi\nu\bar{\nu}(2)$  trigger, the charged-track requirements  $3_{\text{ct}} \cdot 4_{\text{ct}} \cdot 5_{\text{ct}} \cdot 6_{\text{ct}} \cdot (\overline{13_{\text{ct}} + \dots + 18_{\text{ct}}}) \cdot \overline{19_{\text{ct}}}$  ensured hits in range-stack layers  $T$  through 6 to suppress contributions from 3-body  $K^+$  decays and vetoed on hits in the outer layers to suppress long-range charged tracks beyond the  $\pi\nu\bar{\nu}(2)$  kinematic region. The  $\text{TRIG}\pi\nu\bar{\nu}(1)$  trigger condition  $zfrf$  required the  $z$  position of the charged track to be within the fiducial region of all traversed range-stack layers. The  $L0rr1$  and  $L0rr2$  were refined requirements of the charged-track range taking into account the number of target-fiber hits and the track’s  $z$  position in range-stack layers 3, 11, 12, 13 as well as the deepest layer of penetration in order to reject long-range tracks such as the  $\mu^+$  from  $K^+ \rightarrow \mu^+ \nu \mu$  decay. The  $BV$ ,  $BVL$ ,  $EC$ , and  $HEX$  requirements vetoed events with photons in the BV, BVL, EC, and range stack, respectively. The  $L1.1$  used the ratio of the height and area of the pulse(s) recorded by the TD to select the two-pulse signature of the  $\pi^+ \rightarrow \mu^+$  decay in the range-stack counter in which the charged track was determined to have stopped. The  $L1.2$  used data digitized by the range-stack ADCs to reject events with hits near the stopping counter that could falsely satisfy the  $L1.1$  and to reject events with hits in both of the two adjacent hexants when the  $T \cdot 2$  and stopping counter were in the same sector. For the final 60.6% of the data taking, an online pion Čerenkov veto was included in the  $\pi\nu\bar{\nu}(2)$  trigger to mitigate the effect of an increased pion flux caused by reduced electrostatic separator voltage [2].

A subset of the data selected by the  $\pi\nu\bar{\nu}(1+2)$  trigger is shown in Fig. 4.

In addition to TRIG $\pi\nu\bar{\nu}(2)$  and TRIG $\pi\nu\bar{\nu}(1)$ , “monitor” triggers were formed for calibration, monitoring, and acceptance and background measurements [2]. The monitor triggers selected events due to  $K_{\mu 2}$  and  $K_{\pi 2}$  decays as well as scattered beam pions ( $\pi_{\text{scat}}$ ). An additional “CEX” monitor trigger requiring two  $T \cdot 2$  hits was used to collect events resulting from the charge-exchange process  $K^+ n \rightarrow p K_S^0$  followed by  $K_S^0 \rightarrow \pi^+ \pi^-$ . Information derived from this CEX monitor data was used as input to simulation to determine the background from kaon charge-exchange reactions as described in Sec. III C 4. In order to measure the efficiency of the  $T \cdot 2 \cdot IC$  condition (Sec. III D), we also defined a KB monitor trigger that required the KB condition described previously. All monitor triggers were prescaled to reduce their contribution to the dead time.

### III. DATA ANALYSIS

The total exposure for this analysis was  $1.71 \times 10^{12}$  stopped kaons corresponding to  $1.43 \times 10^8$   $\pi\nu\bar{\nu}(1+2)$  triggers. The total exposure was slightly less than the  $1.77 \times 10^{12}$  stopped kaons used for the  $\pi\nu\bar{\nu}(1)$  analysis [2] because some data were discarded due to more strin-

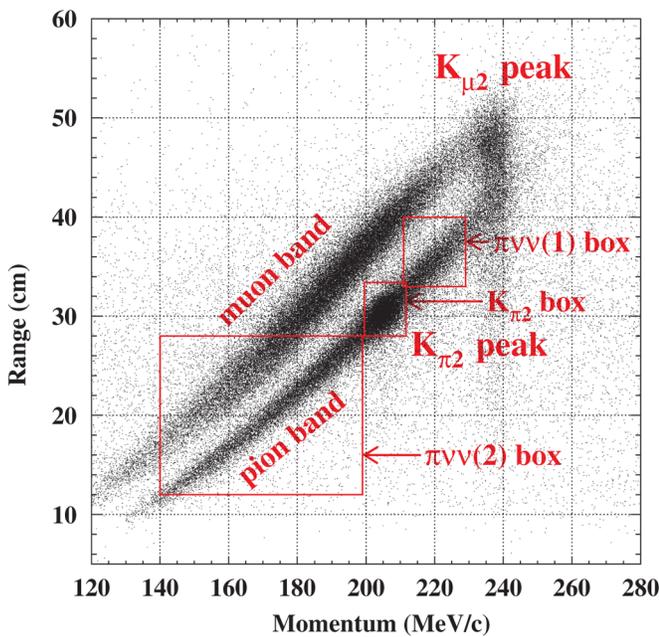

FIG. 4 (color online). Range in plastic scintillator vs momentum for charged particles accepted by the  $\pi\nu\bar{\nu}(1+2)$  trigger. The concentrations of events due to the two-body decays are labeled  $K_{\pi 2}$  peak and  $K_{\mu 2}$  peak. The decays  $K^+ \rightarrow \pi^0 \mu^+ \nu_\mu$  and  $K^+ \rightarrow \mu^+ \nu_\mu \gamma$  contributed to the muon band. The pion band resulted from  $K^+ \rightarrow \pi^+ \pi^0 \gamma$  decays,  $K_{\pi 2}$  decays in which the  $\pi^+$  scattered in the target or range stack and beam  $\pi^+$  that scatter in the target. The boxes at low and high momentum represent the signal regions for this analysis and the previous  $\pi\nu\bar{\nu}(1)$  analysis [2], respectively. This distribution represents 0.13% of the total kaon exposure.

gent requirements on the reliability of the BWPCs, the Cerenkov counter, and the target CCDs.

#### A. Overview

Identification of the  $K^+ \rightarrow \pi^+ \nu\bar{\nu}$  decay involved positive observation of the  $K^+$  and daughter  $\pi^+$  in the absence of coincident detector activity. The  $\pi\nu\bar{\nu}(1)$  and  $\pi\nu\bar{\nu}(2)$  regions in E949 extended from 211 to 229 MeV/c [2] and 140 to 199 MeV/c in  $\pi^+$  momentum below the  $K_{\pi 2}$  peak, respectively (Fig. 4).

The  $\pi\nu\bar{\nu}(2)$  region potentially has a larger acceptance than  $\pi\nu\bar{\nu}(1)$  because the phase space is larger and the loss of  $\pi^+$  due to nuclear interactions in the detector is smaller at lower pion energies. These factors partially mitigated the loss of acceptance due to additional requirements needed to suppress background in the  $\pi\nu\bar{\nu}(2)$  region. Compared to the previous  $\pi\nu\bar{\nu}(2)$  analyses [35,45], the acceptance was increased by enlarging the size of the signal region.

In a further enhancement to the previous  $\pi\nu\bar{\nu}(2)$  analyses [35,45], the signal region was subdivided into regions with differing signal-to-background ratios. The signal-to-background of each region was taken into account in the evaluation of  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu\bar{\nu})$  using a likelihood method (Sec. III E).

#### 1. Kaon-decay background

In the  $\pi\nu\bar{\nu}(1)$  region, the background was dominated by  $K_{\pi 2}$ ,  $K_{\mu 2}$ ,  $K_{\mu 2 \gamma}$ , and  $K_{\mu 3}$  decays and was sufficiently suppressed by positive identification of the  $\pi^+$  based on kinematic properties, observation of the  $\pi \rightarrow \mu \rightarrow e$  sequence, and by the hermetic photon veto capability [2]. Previous studies [35,45] in the  $\pi\nu\bar{\nu}(2)$  region identified the main background as due to  $K_{\pi 2}$  decays in which the charged pion scattered in the target, lost energy, and fell into the signal region. The scatter reduced the directional correlation between the charged and neutral pions. Thus the photons from  $\pi^0$  decay were directed away from the high efficiency barrel region of the photon veto. This background was suppressed, in part, by recognition of the scattering process in the target. A background contribution due to scattering of the charged pion in the range stack was suppressed by the track pattern and energy deposit in the range stack. The photon veto served to suppress these “ $K_{\pi 2}$ -scatter” backgrounds as well as background due to the radiative decay  $K_{\pi 2 \gamma}$ . Background due to  $K^+ \rightarrow \pi^+ \pi^- e^+ \nu_e$  ( $K_{e 4}$ ) was suppressed by identification of additional particles in the target. Kaon decays with a muon in the final state ( $K_{\mu 2}$ ,  $K_{\mu 2 \gamma}$ , and  $K_{\mu 3}$ ) were suppressed by kinematics and the recognition of the  $\pi \rightarrow \mu \rightarrow e$  signature as well as the photon veto for the latter two decays.

#### 2. Beam-related background

The beam-related backgrounds were categorized as being due to CEX, one beam particle (single-beam back-

ground), and two beam particles (double-beam background). The CEX background occurred due to the production of a  $K^0$  in the target from the charge-exchange process  $K^+ n \rightarrow p K^0$ . If the  $K^0$  turned into a  $K_L^0$  that subsequently underwent semileptonic decay ( $K_L^0 \rightarrow \pi^+ \ell^- \bar{\nu}$  with  $\ell^- = e^-$  or  $\mu^-$ ), the  $\pi^+$  could fall in the  $\pi \nu \bar{\nu}(2)$  kinematic region. CEX background was rejected by observing the gap between the kaon and pion fibers due to propagation of the nonionizing  $K_L^0$ , by the inconsistency between the energy deposited by the  $K^+$  and the reconstructed  $z$  of the outgoing pion, and by identification of the accompanying negative lepton. In addition, requirements on the delayed coincidence between the  $K^+$  and  $\pi^+$  suppressed CEX background due to the short  $K_L^0$  flight time.

Single-beam background was due to a  $K^+$  entering the target and decaying in flight to produce a  $\pi^+$  in the  $\pi \nu \bar{\nu}(2)$  region. Incoming beam  $\pi^+$  misidentified as  $K^+$  and scattering in the target also contributed to the single-beam background. Positive identification of the incoming particle as a kaon as well as requirements on the delayed coincidence between the incoming and outgoing tracks suppressed the single-beam background.

The two processes (kaon decay in flight and pion scattering) that contributed to single-beam background formed the double-beam background when preceded by an additional incoming kaon whose decay products were undetected. Double-beam background was suppressed by requiring an absence of activity in the beam detectors in coincidence with the  $\pi^+$  detected in the range stack.

### 3. Analysis method and strategy

We used analysis procedures and strategies similar to that of the E949 analysis of the  $\pi \nu \bar{\nu}(1)$  region [2] with some modification that took into account the difficulty of isolating some background samples in the data in the  $\pi \nu \bar{\nu}(2)$  region. As with the previous analysis, we adopted a “blind” analysis method in that we did not examine the predefined signal region until all background and acceptance analysis was completed. Since we also attempted to obtain all background estimates directly from the data, we inverted at least one selection criteria (“cut”) when we used the  $\pi \nu \bar{\nu}(1+2)$  data to avoid examining the signal region. Every third  $\pi \nu \bar{\nu}(1+2)$  trigger formed the “1/3” sample that was used to determine the selection criteria. We then obtained unbiased background estimates by applying the finalized selection criteria to the remaining “2/3” sample of  $\pi \nu \bar{\nu}(1+2)$  triggers.

The preferred method of background estimation employed the bifurcation method illustrated in Fig. 5. The parameter space of two sets of uncorrelated cuts CUT1 and CUT2 can be divided into the four regions shown in the figure by the application of each cut or the inverted cut. The number of events in the signal region A can be determined by application of both CUT1 and CUT2. If the background rejection of CUT1 was independent of CUT2, then the

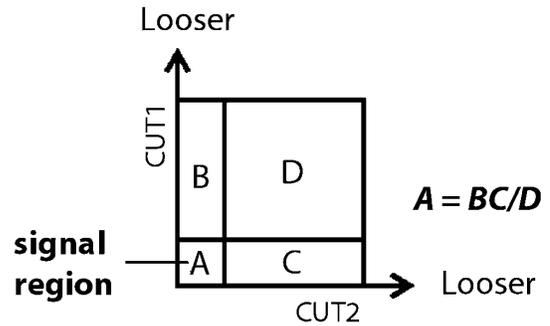

FIG. 5. Schematic of the bifurcation method. The background level in region A can be estimated from the number of events observed in regions B, C, and D assuming CUT1 and CUT2 are uncorrelated. See text for details.

number of events in A can be estimated as the number of events in region B times the ratio of the number of events in regions C and D or  $A = BC/D$ . In practice, we employed two branches for the bifurcation analysis. The “normalization branch” analysis was performed to obtain the number of events,  $N_{\text{norm}}$ , in region B. A “rejection branch” analysis was used to obtain  $D/C$ . We defined the rejection as  $R \equiv (C + D)/C$  and obtained the background estimate as

$$b = f \times N_{\text{norm}} / (R - 1), \quad (3)$$

where  $f = 3(3/2)$  for the 1/3(2/3) sample. For all background estimates in this analysis, the normalization branch was taken from the  $\pi \nu \bar{\nu}(1+2)$  data. We used the  $\pi \nu \bar{\nu}(1+2)$  data to obtain the rejection branch for all backgrounds except for the CEX,  $K_{e4}$ , and  $K_{\pi 2\gamma}$  backgrounds that could not be cleanly isolated in data. For these backgrounds, EGS4-based simulations [46] were employed. When no events ( $N_{\text{norm}} = 0$ ) were available in the normalization branch, we assigned  $N_{\text{norm}} = 1$ .

We checked the validity of the background estimates by loosening cuts and comparing the predicted number of events just outside the signal region with observations (Sec. III C 9). In addition we examined events failing only a single major selection criteria to search for unforeseen background sources and coding mistakes (Sec. III B 8).

## B. Data selection

### 1. Event reconstruction

Event reconstruction was performed in a number of steps consisting of track fitting in various detector systems such as the beamline detectors, the range stack, the UTC, and the target. Multiple iterations of the track fitting were performed in many of the detector systems using progressively better information from track fitting from other detector systems as constraints. Events were reconstructed as described in [2] except as noted below.

The following discussion focuses on the target track fitting to clearly define the target-fiber classification scheme for use in the description of the target CCD fitter and the cuts that used target-fiber information. In contrast to the analysis of the  $\pi\nu\bar{\nu}(1)$  region [2], the fit to the UTC track did not include information from the target fibers. Performing the target fit separately improved the ability to detect a pion scatter in or near the target.

After the range stack and UTC track fitting were performed, target fibers were clustered into  $K^+$  and  $\pi^+$  paths based on geometry, energy, and timing information as shown in Fig. 6. The pion fibers had to lie along a strip (typically 1 cm in width) along the UTC track extrapolated into the target, have an energy between 0.1 and 10.0 MeV, and be in coincidence with the reconstructed time of the  $\pi^+$  in the range stack ( $t_{rs}$ ). For the first iteration, the kaon fibers had to have greater than 4 MeV of energy and be coincident with the beam strobe time. In subsequent iterations, fibers of lower energy which were contiguous with the putative kaon track could be classified as kaon fibers. Any fiber that did not fall into the kaon or pion fiber

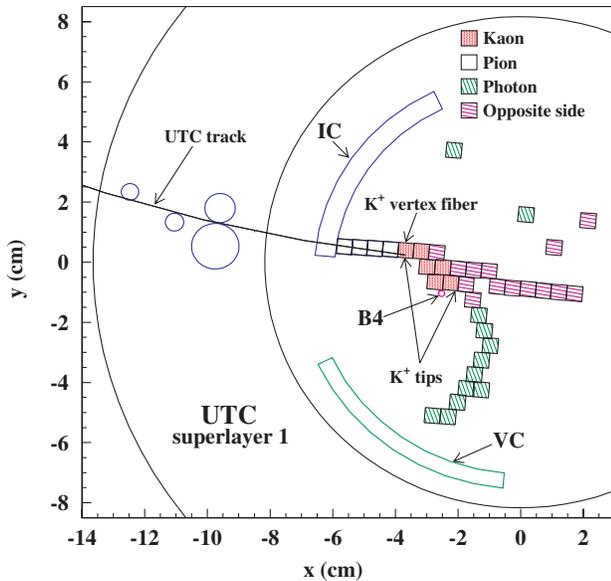

FIG. 6 (color online). Example target  $xy$  display showing the assignment of pion, kaon, photon, and opposite-side pion fibers as described in the text. The arc that terminates in the reconstructed kaon vertex fiber represents the extrapolated UTC track. The circles on the track represent the UTC hits with the radius giving the drift distance. Only the innermost superlayer of the UTC is shown. The IC and VC elements with hits are indicated. The position of the incoming  $K^+$  as reconstructed by the B4 hodoscope information is also indicated in the figure as are the kaon fiber “tips” described in Sec. III B 2. This event was selected in the  $K_{e4}$  normalization branch (Sec. III C 2). The measured time, energy, and apparent curvature of the contiguous fibers classified as “photon” fibers are consistent with a positron and the time and energy of the opposite-side pion fibers are consistent with a negative pion.

categories was classified as a photon fiber if it had more than 0.1 MeV of energy. The  $K^+$  decay vertex fiber was identified as the kaon fiber closest to the extrapolated UTC track and farthest from the  $xy$  position of the B4 hit. Hit fibers that were located on the opposite side of the decay vertex with respect to the outgoing track were classified as “opposite-side pion” fibers and were possibly due to  $K^+$  decays with multiple charged particles or a photon conversion. The energy-weighted average times of the  $K^+$  and  $\pi^+$  hits were  $t_K$  and  $t_\pi$ , respectively. The sums of the  $K^+$  and  $\pi^+$  energies were  $E_K$  and  $E_\pi$ , respectively. The pion and kaon fiber energy distributions are shown in Fig. 7.

Identified pion fibers were subjected to a least-squares fit to the hypothesis of a positively charged pion track [36]. The “target-track fitter” tested the consistency of the energy-loss-corrected UTC track with the energy in the fibers or the distance to the track if the fiber was not on the track.

To aid in the identification of pion scattering in the target, the activity in each of the target fibers as recorded by the low-gain and high-gain CCDs (Sec. II A) was fitted using a single-pulse and a double-pulse hypothesis. For each CCD on each fiber, a standardized  $K^+$  pulse used for the target CCD fitter was created using kaon fiber data from  $K_{\mu 2}$  monitor trigger data. For each fiber having an energy greater than a fiber-dependent threshold, typically 2 (0.5) MeV for low (high) gain, the fitting procedure was performed on the low-gain and the high-gain CCD information independently. The first step of the procedure was a least-squares fit to a single-pulse hypothesis for each fiber channel passing the above criteria. The single-pulse fit used two parameters, the pulse amplitude and the time. If

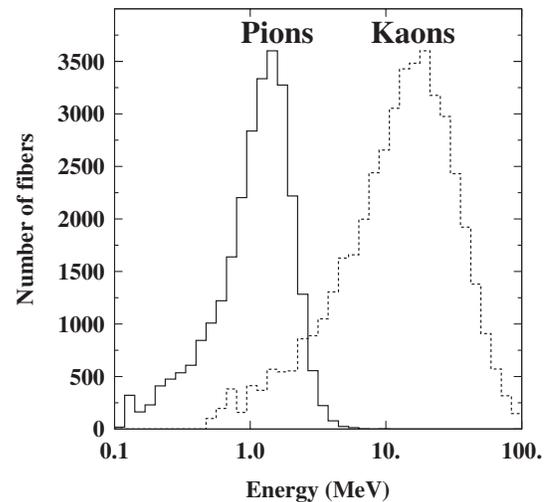

FIG. 7. The energy per pion fiber or kaon fiber in events in the  $K_{\pi 2}$ -peak region, defined in Sec. III B 4, in  $\pi\nu\bar{\nu}(1+2)$  triggers. The height of the pion energy distribution was normalized to that of the kaon energy distribution for the purpose of display. The average number of pion (kaon) fibers per event in the selected events is 10.2 (5.3). Note the logarithmic abscissa.

the probability of  $\chi^2$  ( $\mathcal{P}(\chi^2)$ ) of the single-pulse fit was less than 25%, a double-pulse fit was performed. The double-pulse fit used four parameters, the amplitudes and times for the first and second pulses.

## 2. Requirements on $\pi^+$ in target

Numerous requirements were placed on the activity in the target to suppress background and ensure reliable determination of the kinematic properties of the charged pion. These requirements were based on the results of the target CCD fitter, the reconstructed energy and time of the pion and kaon fibers, the pattern of kaon and pion fibers relative to information from the rest of the detector and the results of the target-track fitter.

*Target-pulse data analysis.*—Detection of pion scattering in the target in the identified kaon fibers required reliable results from the target CCD fitter. An algorithm, based on the energy in the kaon fiber as measured by the ADC and by the time difference  $t_\pi - t_K$ , determined if the information from the high-gain CCD, the low-gain CCD, or a combination of the two should be used for each fiber with an acceptable double-pulse fit. If  $\mathcal{P}(\chi^2)$ 's of the fits for both the single- and double-pulse hypotheses were less than  $5 \times 10^{-5}$  in any of the kaon fibers, then the event was rejected. In addition, the fitted time of the first pulse ( $t_1$ ) was required to be consistent with the average time of the kaon fibers. If any kaon fibers failed the requirement  $-6 < t_1 - t_K < 7$  ns, then the event was rejected. This requirement was made on the fitted time  $t_1$  of the single-pulse hypotheses if the probability of  $\chi^2$  was greater than 25% and on the fitted time  $t_1$  from the double-pulse hypothesis otherwise. The requirement on  $t_1$  rejected events in which the CCD fitter attempted to fit a fluctuation in the tail of the data pulse or when there was a large second pulse and the fitter mistakenly identified it as the first pulse. For events passing these criteria, the second-pulse activity in a kaon fiber as found by the target CCD fitting was required to be below 1.25 MeV when the fitted second-pulse time  $t_2$  satisfied the coincidence condition  $-7.5 \leq t_2 - t_\pi \leq 10$  ns. An example of the fit for a high-gain CCD target element is shown in Fig. 8. In the following we refer to these requirements on the CCD pulse fitting as the ‘‘CCDPUL’’ cut.

*Kaon fiber timing.*—The target kaon fiber hits were required to be consistent with a kaon approaching the  $K^+$  decay vertex. This consistency was enforced by requiring  $\mathcal{P}(\chi^2)$  to be greater than 5% for fits to the kaon fiber hit times vs  $xy$  distance to the decay vertex and vs range. This requirement removed events in which the kaon-decay vertex was incorrectly assigned.

*Pion fiber energy.*—Pion fibers were required to have energies less than 3.0 MeV. This suppressed  $\pi^+$  target scatters since the expected mean energy deposited in a pion fiber was approximately 1.2 MeV. This cut had an acceptance factor of 89.6% (Sec. III D 2) due to the Landau distribution that describes the ionization energy deposit.

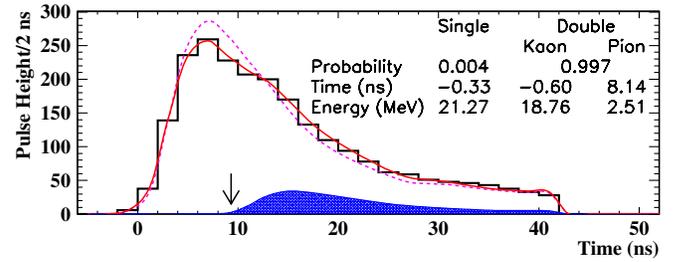

FIG. 8 (color online). CCD pulse fit example. The histogram represents the pulse height distribution for the high-gain CCD data. The histogram was terminated at 42 ns due to a software cutoff. The dashed (solid) line represents the fitted total pulse shape for the single- (double-) pulse hypothesis. The filled area represents the fitted second pulse for the double-pulse hypothesis. The arrow indicates  $t_{rs}$ , the expected time of the second pulse based on the reconstructed  $\pi^+$  in the range stack. This event was rejected because the 2.5 MeV of the fitted second pulse was coincident with  $t_{rs}$ .

The measured range and energy of the pion and the pion momentum were required to be consistent with that expected for a  $\pi^+$  using a cut on a likelihood function. The likelihood function was calibrated using  $\pi_{scat}$  monitor trigger events. In addition, the total energy of the pion target fibers was required to be in the range of 1 to 28 MeV and the total energy within  $\pm 4.0$  ns of  $t_{rs}$  in the target edge fibers was required to be less than 5.0 MeV.

*Pattern of kaon and pion fibers.*—Events with a minimum distance between the centers of the closest pair of kaon and pion fibers greater than 0.6 cm, more than one fiber width, were rejected. This cut suppressed the CEX background. A more stringent version of this cut that also required that no photon fibers filled the gap between the kaon and pion fibers was developed to define the normalization branches for the CEX (Sec. III C 4) and double-beam (Sec. III C 6) background measurements.

Two conditions were used to enforce consistency among the positions of the kaon-decay vertex, the kaon and pion clusters, and the beam particle in the B4 hodoscope. The first condition required that the distance in the  $xy$  plane between the hit position in the B4 hodoscope and the nearest tip of the kaon fiber cluster be less than 1.8 cm. The kaon cluster tips were defined to be the two kaon fibers farthest apart from each other (Fig. 6). The second condition required that the distance in the  $xy$  plane between the kaon-decay vertex and the nearest kaon cluster tip was less than 0.7 cm. This requirement suppressed  $K_{\pi 2}$  target-scatter background when the scattered  $\pi^+$  did not emerge from the fiber containing the  $K^+$  decay.

The total energy of opposite-side pion fibers within  $\pm 4.0$  ns of  $t_\pi$  was required to be less than 1.0 MeV to suppress background due to  $K_{e4}$  decays as well as  $K_{\pi 2}$  scatters. Hereafter, this cut is referred to as ‘‘OPSVETO.’’

*Target-track fitter.*—The track determined by the target-track fitter was required to be consistent with the informa-

tion in the target fibers and the fitted UTC track in order to suppress backgrounds due to pion scattering, CEX,  $K_{e4}$ , or a second beam particle in the target. For three contributions  $\chi_5^2$ ,  $\chi_6^2$ , and  $\chi_7^2$  to the  $\chi^2$  for the target-track least-squares fit,  $\mathcal{P}(\chi_5^2 + \chi_6^2 + \chi_7^2)$  was required to be greater than 1%. These were defined as follows:

- (i)  $\chi_5^2$  was assigned a contribution for each pion fiber traversed by the track based on the comparison of the observed energy with the expected energy from the calculated range of the track and the track momentum.
- (ii)  $\chi_6^2$  was assigned a contribution based on the minimum distance between the track and the nearest point of each fiber that was traversed by the track, but had no observed energy. This assignment acted to force the fitted track to go between fibers and thus provided precise position information on the track.
- (iii)  $\chi_7^2$  was assigned a contribution for pion fibers that were not traversed by the fitted track based on the distance to the nearest corner.

Events were rejected if any single pion fiber contributed more than 35 units to  $\chi_5^2$  which might indicate a pion scatter in that fiber. The fitted target track was also required to intersect the kaon vertex fiber. The angle between the reconstructed target track and the UTC track was required to be less than 0.01 rad at the radius of the IC when the range of the  $\pi^+$  in the target was less than 2.0 cm. In addition, the position of the reconstructed  $\pi^+$  trajectories from the target and UTC fits were required to be well matched at the target edge. Events with a kink in the target  $\pi^+$  track were suppressed by requiring that the difference in the distances in the  $xy$  plane of the farthest and nearest pion fibers to the center of the fitted helix of the UTC track was less than 0.35 times the pion range in the target.

### 3. Pion track requirements

Good pion track reconstruction was required based on the  $\chi^2$  of the UTC track fit. The cut on the  $\chi^2$  was dependent on the number of anode and cathode hits assigned to the fitted track as well as on the number of unused anode and cathode hits. The criteria were determined using both  $K_{\pi 2}$  and  $\pi_{\text{scat}}$  monitor trigger data such that the  $\pi^+$  momentum resolution of 2.3 MeV/ $c$  for the  $K_{\pi 2}$  peak [2] was maintained while retaining high efficiency.

Range-stack quality cuts were placed on the probability of  $\chi^2$  of the range-stack track fit and the agreement of the  $z$  position of the extrapolated UTC track with the range-stack timing information and, when applicable, the RSSC information. The RSSC was not available for charged particles that stopped in range-stack layers 6–10.

Kaons that came to rest in the target were required to have energy loss in the B4 hodoscope and the target consistent with the measured  $K^+$  stopping position based on the  $z$  position of the extrapolated UTC track. A likelihood function based on these three quantities was calibrated

using  $K_{\mu 2}$  monitor trigger data. The requirement on this “beam likelihood” function suppressed  $K_{\pi 2}$  target-scatter and CEX backgrounds as well as background due to an incoming beam pion that scattered in the target. In addition, we required the  $z$  of the extrapolated UTC track to be greater than  $-5.0$  cm as shown in Fig. 9. Since other cuts more effectively suppressed background from the downstream portion of the target ( $10 < z < 20$  cm), no explicit additional cut on  $z$  was necessary.

### 4. Decay pion kinematic requirements

The total range (kinetic energy) of the  $\pi^+$  track was calculated as the sum of the measured range (energy) in the target, IC, and range stack. The total momentum was obtained from the curvature of the fitted track in the UTC corrected for energy loss in the target and IC. Tiny corrections were applied to  $R_\pi$ ,  $E_\pi$ , and  $P_\pi$  to take into account the inactive material in the UTC [2].

The upper limit of the signal region in range, energy, and momentum was increased with respect to the previous  $\pi\nu\bar{\nu}(2)$  analyses [35,45] to be approximately 2.5 standard deviations from the  $K_{\pi 2}$  peak similar to the approach used for the E949  $\pi\nu\bar{\nu}(1)$  analysis [2]. The lower limits were not changed with respect to the previous  $\pi\nu\bar{\nu}(2)$  analyses. The standard signal region was  $140 < P_\pi < 199$  MeV/ $c$ ,  $60 < E_\pi < 100.5$  MeV, and  $12 < R_\pi < 28$  cm.

To increase the statistical power of any observed signal events (Sec. III E), a tighter kinematic region was defined as a subset of the standard region to further suppress  $K_{\pi 2}$

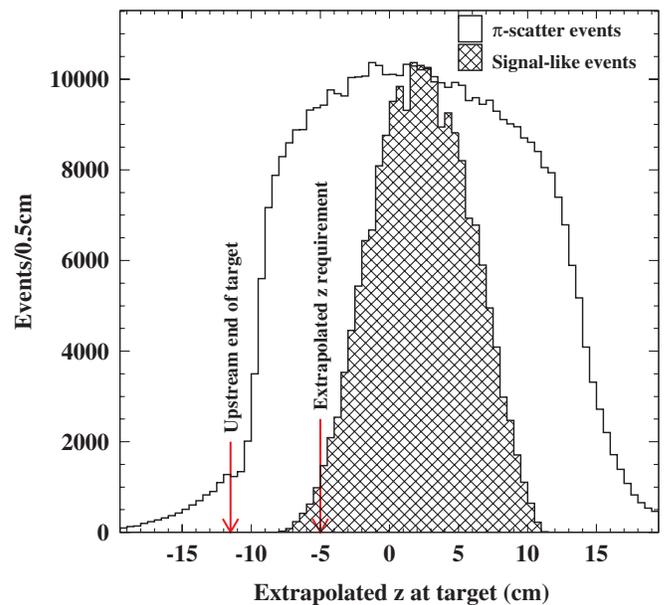

FIG. 9 (color online). Extrapolated target  $z$  distribution of the charged track. The “ $\pi$ -scatter” and “signal-like” events are taken from  $\pi_{\text{scat}}$  and  $K_{\mu 2}$  monitor trigger data, respectively. The required minimum on the extrapolated  $z$  position and the upstream end of the target are indicated in the figure.

and  $K_{e4}$  backgrounds. As discussed in Sec. III C 2,  $K_{\pi 2}$  and  $K_{e4}$  events were not uniformly distributed in the signal region. The  $K_{\pi 2}$  target-scatter events were more uniformly distributed in the signal region except near the  $K_{\pi 2}$  peak. The imposition of the  $\pi \nu \bar{\nu}(1+2)$  trigger on the  $K_{e4}$  momentum distribution shown in Fig. 1 caused the  $K_{e4}$  background to peak around 160 MeV/c as described in Sec. III C 2. The accepted  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  spectrum was monotonically increasing with momentum in the signal region (Fig. 17). Based on these observations, the kinematic region that maximized the ratio of the signal acceptance to the total  $K_{\pi 2}$  and  $K_{e4}$  background was  $165 < P_\pi < 197$  MeV/c,  $72 < E_\pi < 100$  MeV, and  $17 < R_\pi < 28$  cm.

We also defined the “ $K_{\pi 2}$ -peak region” by the requirements  $199 < P_\pi < 215$  MeV/c,  $100.5 < E_\pi < 115$  MeV, and  $28 < R_\pi < 35$  cm (Fig. 4). Events in the  $K_{\pi 2}$ -peak region were employed to set selection criteria, estimate background, and determine the signal acceptance.

### 5. Muon identification

Muon backgrounds were rejected largely based upon the positive identification of the  $\pi^+$  in the range stack by the observation of the  $\pi \rightarrow \mu \rightarrow e$  decay chain and by the range-momentum relationship.

The  $\pi^+$  identification algorithms of  $\pi \nu \bar{\nu}(1)$  [2] were adopted for this analysis, and only a brief description is provided here. The analysis of the waveform provided by the transient digitizers (TDs) was used to identify the  $\pi^+ \rightarrow \mu^+ \nu_\mu$  decay in the range-stack element that contained the stopping pion. A neural network was trained using kinematically identified  $\pi^+$  and  $\mu^+$  that stopped in the range stack [2]. The  $\mu^+ \rightarrow e^+ \nu_e \bar{\nu}_\mu$  decay was identified by TDC information in the range-stack counters near the stopping counter.

Since the previous  $\pi \nu \bar{\nu}(2)$  analyses [35,45] had shown that muon backgrounds were small, less restrictive requirements on the  $\pi \rightarrow \mu \rightarrow e$  decay than those in the  $\pi \nu \bar{\nu}(1)$  analysis were used for the standard  $\pi \nu \bar{\nu}(2)$  requirements. This provided a 10% increase in the signal acceptance. A muon rejection of  $133.0 \pm 10.7$  (Sec. III C 3) was obtained with a looser requirement on the neural network output and no identification of the  $\mu \rightarrow e$  decay. The  $\pi \nu \bar{\nu}(1)$  requirements were used to define a tighter cut that was used to subdivide the signal region as described in Sec. III E. The tighter cuts had a muon rejection of  $409.1 \pm 60.9$ . In the following we refer to the  $\pi \rightarrow \mu \rightarrow e$  requirements as the “TD” cuts.

The ability to separate pions from muons using the range and momentum measurements can be seen in Fig. 4. The separation was based on the “RNGMOM” cut that was placed on the quantity  $\chi_{rm} = (R_{rs} - R_{UTC})/\sigma_R$  where  $R_{UTC}$  ( $\sigma_R$ ) was the expected range (uncertainty in range) for a given  $\pi^+$  momentum and  $R_{rs}$  was the measured range in the range stack.

### 6. Delayed-coincidence requirements

Determining that the incoming  $K^+$  came to rest in the target was accomplished by observing the delay between the incoming particle and the outgoing charged track. This requirement rejected incoming beam pions that scattered in the target as well as the products of  $K^+$  decay in flight. The delayed coincidence also served to suppress the CEX background.

For the standard delayed-coincidence requirement, the average time of the kaon fiber hits ( $t_K$ ) had to be at least 3 ns earlier than the average time of the pion fiber hits ( $t_\pi$ ). The previous  $\pi \nu \bar{\nu}(2)$  analyses [35,45] used a tighter requirement of  $t_\pi - t_K > 6$  ns. The looser requirement in this analysis resulted in a 9% relative acceptance increase. Since under certain conditions the resolution on  $t_K$  or  $t_\pi$  was degraded, the degraded time resolution was taken into account by increasing the minimum delayed coincidence allowed. It was increased to 4 ns when the energy deposit in the target kaon fibers was less than 50 MeV, when the time of any of the individual kaon fiber differed from the average kaon fiber time by more than 2 ns or when the time of an individual target pion fiber differed from the average time of the pion fiber hits by more than 3.5 ns. It was increased to 5 ns when the difference between  $t_K$  and the B4 hodoscope hit time was greater than 1 ns or when  $t_\pi$  was determined using IC hit time because the average time of the pion fiber hits had poor resolution. It was increased to 6 ns when the difference between  $t_\pi$  and  $t_{rs}$  was greater than 1.5 ns.

A tight version of the delayed coincidence with the requirement of  $t_\pi - t_K > 6$  ns was used to subdivide the signal region as described in Sec. III E.

### 7. Photon veto requirements

An event was rejected by the photon veto cut when the total energy in a subdetector within a time window exceeded a given threshold. The time window was referenced to  $t_{rs}$ , the reconstructed time of the pion in the range stack. The time window and energy threshold were set for each subdetector using an optimization algorithm described in [2]. The end caps were treated as three separate subdetectors EC<sub>outer</sub>, EC<sub>inner</sub>, and EC<sub>2nd</sub> in the optimization. EC<sub>inner</sub> was the inner ring of the upstream EC and had higher accidental rates than the remaining EC elements due to its proximity to the incoming beam. EC<sub>2nd</sub> was the EC energy identified by a double-pulse-finding algorithm using CCD information. EC<sub>outer</sub> comprised the EC elements not included in EC<sub>inner</sub>. The optimization procedure determined the rejection and acceptance as the time window and energy threshold were varied. The optimization goal was to maximize rejection for a given value of acceptance. The acceptance sample used by the optimization procedure was derived from  $K_{\mu 2}$  monitor trigger data.

The photon veto requirements for the  $\pi \nu \bar{\nu}(1)$  analysis were optimized using  $K_{\pi 2}$ -peak events that were the domi-

nant background with photons. Ideally the  $\pi\nu\bar{\nu}(2)$  photon veto requirements would have been optimized on a sample of  $K_{\pi 2}$  target-scatter events; however, given that photon veto rejection needed to be  $\mathcal{O}(2500)$ , we were unable to prepare such a sample with sufficient statistics,  $\mathcal{O}(250\,000)$  events, needed to minimize bias in the optimization result. In lieu of this sample, we optimized the photon veto requirements for a majority of subdetectors using a sample of  $K_{\pi 2}$ -peak events and then optimized the requirements for the remaining subdetectors using multiple samples of  $K_{\pi 2}$  target-scatter events as described below.

The main sample of  $K_{\pi 2}$  target-scatter events failed either the CCDPUL cut (Sec. III B 2) or the beam likelihood cut (Sec. III B 3) and contained 26 317 and 52 621 events in the 1/3 and 2/3 data samples, respectively. Other  $K_{\pi 2}$  target-scatter samples were composed of events failing these cuts or the other target cuts described in Sec. III B 2. The size of the other samples ranged from 11 037 (22 037) to 29 899 (59 871) in the 1/3 (2/3) data samples. These samples overlapped one another, but they contained pions with different relative populations of the pion scattering angle with respect to the beam direction.

An additional sample, dubbed the “kink” sample containing  $K_{\pi 2}$  target scatters where the  $\pi^+$  track had an identifiable kink in the  $xy$  projection, was created by processing every  $\pi\nu\bar{\nu}(1+2)$  event with a kinked-track reconstruction algorithm. For kink reconstruction, the restrictions on the pion fiber energy were removed as well as the requirement that the pion fibers had to be within 1 cm of the extrapolated UTC track. The following criteria defined a valid kink event: (1) the event had at least two pion fibers that deviated from the UTC extrapolation, (2) at least one of the fibers from (1) must be adjacent to a kaon fiber, (3) the remaining pion fibers must be along the UTC extrapolation, and (4) the event must be rejected by the criteria placed on the standard target-track reconstruction. The final criterion guaranteed that the kink sample was independent of the sample of signal events and the other samples described in the previous paragraph. Although the resulting kink sample had only 11 833 events, it provided a sample rich in target scatters that was used in understanding the response of the AD as described below.

Before beginning the photon veto optimization procedure, we applied a cut on the activity in the BV prior to  $t_{rs}$  ( $BV_{\text{early}}$ ) because a large energy deposit ( $> 30$  MeV) in the BV prior to the kaon decay would prevent the TDCs from registering activity coincident with  $t_{rs}$  [47]. The  $\pi\nu\bar{\nu}(1)$  set of parameters as listed in Table VI of [2] was the starting point for the  $\pi\nu\bar{\nu}(2)$  optimization that included all subdetectors except the AD and DPV. Primary and secondary sets of parameters were determined for the 11 subdetectors listed in Table I.

The AD parameters were determined using the kink sample after application of a photon veto cut with a rejection of approximately 175 with looser settings on the parameters of the other subdetectors. These AD parameters

yielded an additional photon veto rejection on the main  $K_{\pi 2}$  target-scatter sample of  $1.95 \pm 0.08$  with a 94% acceptance factor [47]. The main  $K_{\pi 2}$  target-scatter sample was also used to optimize the DPV parameters. After application of all other photon veto parameters at the primary setting listed in Table I, the DPV rejection was measured to be  $1.13 \pm 0.09$  with an acceptance factor of 99.99%.

The  $BVL_{\text{same}}$  cut was devised subsequent to the single-cut failure study on the 1/3 sample (Sec. III B 8). The cut removed potential  $K_{\pi 2}$  background when both photons from the  $\pi^0$  decay deposited energy in the same BVL element. Such an occurrence yielded a reconstructed time earlier than  $t_{rs}$ , a reconstructed  $z$  position near the center of the element and an apparent energy greater than 10 MeV.

Figure 10 shows the off-line rejection for fixed values of the total (on-line and off-line) acceptance for the photon veto. The parameters in the primary column in Table I corresponded to the standard photon veto cut (“standard” in the figure). For the more restrictive (“tight”) photon veto cut described in Sec. III E, events were rejected that failed the criteria established by either the primary or the secondary parameters. Of the additional settings labeled “loose” and “ $\pi\nu\bar{\nu}(1)$ ” in the figure, the photon veto cuts were used for background estimation (Sec. III C 3) and consistency checks (Sec. III C 9).

TABLE I. Time window and energy threshold of the primary and secondary photon veto requirements for each subdetector as described in the text. The time window was defined with respect to  $t_{rs}$ , the reconstructed time of the  $\pi^+$  in the range stack. RS and TG label the range stack and target parameters, respectively. The parameters for the subdetectors in the last four rows were optimized separately as described in the text.  $BVL_{\text{same}}$  had the additional requirement that the reconstructed  $z$  position satisfies  $|z| < 4$  cm.

### 8. Single-cut failure study

After determination of the selection criteria using the 1/3 data sample, we performed a “single-cut” failure study to identify unexpected sources of background or potential analysis flaws. Individual cuts that exploited similar background characteristics were grouped together to form the following 12 cut categories:

- (1) the cuts on  $R_\pi$ ,  $P_\pi$ , and  $E_\pi$  (Sec. III B 4),
- (2) all photon veto cuts except those on the AD and target,
- (3) the photon veto cut on the AD,
- (4) the target photon veto and OPSVETO (Sec. III B 2) cut,
- (5) the delayed-coincidence cut (Sec. III B 6),
- (6) the  $\pi/\mu$  range-momentum separation requirement (Sec. III C 3) and the pion track requirements (Sec. III B 3) excluding the cuts in the next two categories,
- (7) the beam likelihood cut (Sec. III B 3),
- (8) the cut requiring the  $z$  position of the extrapolated UTC track to be more than 6.5 cm from the upstream end of the target (Sec. III B 3),
- (9) the CCDPUL and kaon fiber timing cuts (Sec. III B 2),
- (10) the cuts related to the identification of the  $\pi \rightarrow \mu \rightarrow e$  decay chain,
- (11) the cuts to suppress beam-related backgrounds,
- (12) the cuts on pion fiber energy, the pattern of kaon and pion fibers, and the target-track fitter (Sec. III B 2).

All events in the 1/3 data sample that failed only one of these 12 categories were examined. We found four events that contained evidence of two potential analysis flaws.

Three of the events not rejected by the photon veto cuts showed evidence of a large energy deposit in the BVL. These events were shown to be due to  $K_{\pi 2}$  decays in which both photons from the  $\pi^0$  decay deposited energy in the same BVL counter [48]. The simultaneous activity at each end of a BVL element led to an erroneous average time prior to  $t_{rs}$  that was outside the veto time window. The “BVL<sub>same</sub>” cut, previously described in Sec. III B 7, was devised to remove these events.

The remaining event of the four failed only the photon veto criteria in the AD and revealed a potential flaw in the CCDPUL target-pulse fitting algorithm when the fitted time of the first pulse was inconsistent with the average kaon fiber time. The inconsistency arose when the fitting algorithm incorrectly assigned the first pulse time to an actual second pulse because the second pulse energy was larger than the first pulse energy. The CCDPUL timing criteria already described in Sec. III B 2 were developed to remove the analysis flaw.

No analysis flaws or unexpected sources of background were revealed by the “single-cut” failure study of the 2/3 data sample.

## C. Backgrounds

### 1. $K_{\pi 2}$ -related background

The  $K_{\pi 2}$ -related background contained three components:  $K_{\pi 2}$  target scatter,  $K_{\pi 2}$  range-stack scatter, and  $K_{\pi 2\gamma}$ . In order to have a  $K_{\pi 2}$  event in the signal region, the photons from the  $\pi^0$  decay had to escape detection and the  $\pi^+$  had to lose energy via scattering or resolution effects such that it fell into the signal phase space. Scattering could happen in the target ( $K_{\pi 2}$  target scatter) or in the range stack ( $K_{\pi 2}$  range-stack scatter). The target-scatter component dominated in the background. Since the  $\pi^+$  from a  $K_{\pi 2\gamma}$  decay was not monochromatic, the three final-state photons needed to escape detection for this type of event to be a background.

The topology of the most problematic type of  $K_{\pi 2}$  target scatter was that of a  $\pi^+$  initially traveling in the kaon fibers and scattering into the barrel region of the detector as indicated schematically in Fig. 11. This type of target scatter was difficult to reject because some energy deposited in the target by the scattering  $\pi^+$  occurred in a kaon fiber (Sec. III B 2) and could not always be distinguished from the larger energy deposited by the stopping kaon (Fig. 7). In addition, the  $\pi^0$  was also traveling parallel to the beam direction and the resulting photons from the  $\pi^0$  decay were directed at the upstream or downstream ends of the detector where the photon veto was less efficient.

In the  $K_{\pi 2}$  target-scatter background estimate, the two bifurcation cuts chosen were the standard photon veto cuts (CUT1) and the target-quality cuts (CUT2), since both of these gave powerful rejection of the  $K_{\pi 2}$  target-scatter background. The bifurcation analysis sample was prepared by applying cuts to remove the contamination from muon,

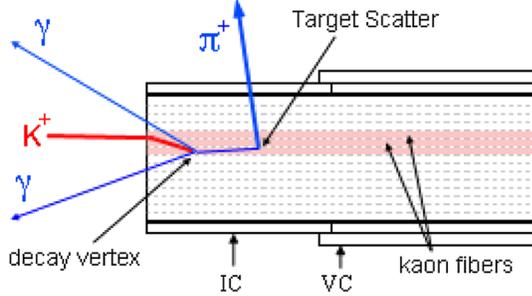

FIG. 11 (color online). Schematic representation of a  $K_{\pi 2}$  target scatter in which the  $\pi^+$  initially traveled in the  $z$  direction, scattered in a kaon fiber, and was directed into the barrel region. The two photons from the decay of the recoiling  $\pi^0$  were directed into the beam region.

beam, and charge-exchange events. In the normalization branch, a combination of  $K_{\pi 2}$  target scatter,  $K_{\pi 2}$  range-stack scatter, and  $K_{\pi 2\gamma}$  events were selected by inverting the photon veto cuts (CUT1). All the target-quality cuts (CUT2) were applied to the sample, resulting in 1131 events left in the normalization branch in the 2/3 sample. After corrections for  $K_{\pi 2}$  range-stack-scatter contamination (detailed below),  $N_{\text{norm}} = 1107.7 \pm 33.8(\text{stat})_{-2.8}^{+2.9}(\text{syst})$  events remained in the normalization branch. The systematic uncertainty is due to the correction for range-stack scatters. Corrections for contamination due to  $K_{\pi 2\gamma}$  are discussed later in this section.

For the  $K_{\pi 2}$  target-scatter rejection branch, the  $K_{\pi 2}$  target-scatter events were classified into two nonexclusive categories. The first category, “ $z$  scatter,” occurred when the  $\pi^+$  traveling parallel or antiparallel to the beam direction scattered in a kaon fiber into the barrel region of the detector as depicted in Fig. 11. The second category, “ $xy$  scatter,” occurred when the  $\pi^+$  scattered outside of the kaon fibers, and the scatter was visible in the  $xy$  plane. To measure the rejection of the photon veto for target-scatter events, six classes of  $K_{\pi 2}$  target-scatter events containing varying mixtures of  $xy$ -scatter and  $z$ -scatter events were created by applying or inverting various combinations of the requirements on  $\pi^+$  in the target (Sec. III B 2). The primary  $K_{\pi 2}$  target-scatter sample (Sec. III B 7), considered to be the richest in  $z$  scatters, was chosen to measure the photon veto rejection, giving 52 621 events for the region  $C + D$  (Fig. 5). The photon veto cuts (CUT1) were then applied to the remaining  $K_{\pi 2}$  target-scatter events, leaving 22 events for the region  $C$  for a rejection of  $52\,621/22 = 2392 \pm 510$ , where the uncertainty is statistical only. The pion momentum distributions of the normalization and rejection branches are shown in Fig. 12. The photon veto rejections measured in the other five classes of target-scatter events were consistent with that of the primary sample and extended from a minimum of  $2204 \pm 697$  to a maximum of  $2758 \pm 650$ . The photon veto rejection of the main  $K_{\pi 2}$  target-scatter sample in the

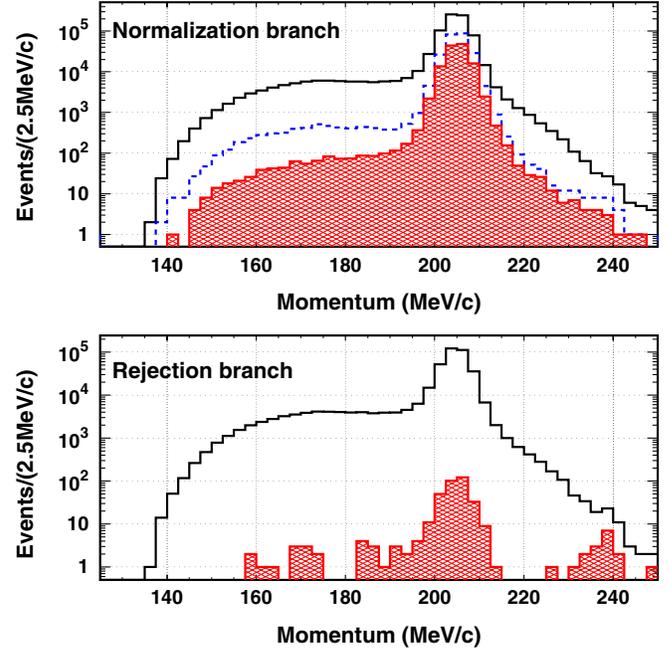

FIG. 12 (color online). (Top panel) Pion momentum distribution for the normalization branch in the 2/3 data sample. The black histogram represents the distribution after inversion of the photon veto cut. The blue dashed histogram shows the suppression of all the target cuts except for the CCDPUL cut and the red shaded histogram shows the suppression of all the target cuts including the CCDPUL cut. (Bottom panel) Pion momentum distribution of the rejection branch in the 2/3 data sample. The events obtained from the inversion of the target cuts are shown in black and the red shaded histogram shows the events that survive the photon veto cut that peak near 236 MeV/c were due to  $K_{\mu 2}$  decays. The cuts on pion kinetic energy and range were not applied for these distributions in order to show the momentum distribution outside the  $\pi\nu\bar{\nu}(2)$  signal region.

tighter kinematic region (Sec. III B 4) was measured to be  $2193 \pm 517$  in agreement with the measurement in the standard kinematic region. The range of measured rejection values in the other five classes was used to set the systematic uncertainty in the photon veto rejection on the  $K_{\pi 2}$  target-scatters, giving a photon veto rejection of  $2392 \pm 510_{-188}^{+366}$ . Using Eq. (3), the uncorrected number of  $K_{\pi 2}$  target-scatter background events was measured to be

$$b_{\text{un}}^{\text{tg}} = 3/2 \times (1107.7 \pm 33.8_{-2.8}^{+2.9}) / ((2392 \pm 510_{-188}^{+366}) - 1) = 0.695 \pm 0.150_{-0.100}^{+0.067}, \quad (4)$$

where the first uncertainty was statistical and the second uncertainty systematic.

For the  $K_{\pi 2}$  range-stack-scatter background events, the cuts with the most powerful rejection were the range-stack track quality and the photon veto cuts. The  $K_{\pi 2}$  range-

stack-scatter normalization branch was a modified version of the  $K_{\pi 2}$  target-scatter normalization branch, with the range-stack quality cuts inverted instead of being applied before the inversion of the photon veto cut as was done in the  $K_{\pi 2}$  target-scatter normalization branch. This sample of  $N_2 = 281$  events was heavily contaminated with target-scatter events due to the inefficiency of the range-stack-scatter cuts. The  $N_1 = 1131$  events remaining at the end of the  $K_{\pi 2}$  target-scatter normalization branch consisted of  $N^{\text{tg}}$  target-scatter events with contamination due to  $N^{\text{rs}}$  range-stack-scatter events:

$$N^{\text{tg}} + N^{\text{rs}} = N_1. \quad (5)$$

These  $N^{\text{tg}}$   $K_{\pi 2}$  target-scatter events and  $N^{\text{rs}}$   $K_{\pi 2}$  range-stack-scatter events were also related to the  $N_2$  events remaining in the  $K_{\pi 2}$  range-stack-scatter normalization branch by

$$\frac{1 - A^{\text{rs}}}{A^{\text{rs}}} \times N^{\text{tg}} + (R^{\text{rs}} - 1) \times N^{\text{rs}} = N_2, \quad (6)$$

where  $A^{\text{rs}} = 0.888 \pm 0.001(\text{stat}) \pm 0.012(\text{syst})$  was the acceptance factor for the range-stack quality cuts, and  $R^{\text{rs}} = 7.06 \pm 0.47$  was the rejection of  $K_{\pi 2}$  range-stack-scatter events by the range-stack quality cuts measured using events with momentum consistent with the  $K_{\pi 2}$ -peak region, but range and energy in the  $\pi \nu \bar{\nu}(2)$  signal region as would be expected for a range-stack scatter. The systematic uncertainty on  $A^{\text{rs}}$  was due to the larger uncertainty on the measured kinematics of the  $\pi_{\text{scat}}$  monitor data used to measure the acceptance of the range-stack quality cuts as described in Sec. III D. By solving Eqs. (5) and (6) simultaneously, it was possible to estimate the number of  $K_{\pi 2}$  target-scatter events ( $N^{\text{tg}} = 1107.7 \pm 33.8^{+2.9}_{-2.8}$ ) and the number of  $K_{\pi 2}$  range-stack-scatter events ( $N^{\text{rs}} = 23.3 \pm 3.5^{+2.9}_{-3.0}$ ) present in the original  $K_{\pi 2}$  target-scatter normalization branch, where the first uncertainty is statistical and the second is systematic due to the acceptance factor  $A^{\text{rs}}$ .

The photon veto rejection on the  $K_{\pi 2}$  range-stack-scatter events should be the same as that for the unscattered  $K_{\pi 2}$ -peak events as the back-to-back correlation of the  $\pi^+$  and  $\pi^0$  was maintained. The  $K_{\pi 2}$  range-stack-scatter rejection branch was created by applying all cuts other than the photon veto cuts and the pion kinematic cuts (Sec. III B 4). The  $K_{\pi 2}$ -peak region events were selected, creating a sample of 122 581 events for the region  $C + D$ . The PV cuts (CUT1) were then applied to the remaining  $K_{\pi 2}$  events, leaving 106 events in region  $C$  for a photon veto rejection of  $122\,581/106 = 1156 \pm 112$ . The number of  $K_{\pi 2}$  range-stack-scatter background events was measured to be

$$\begin{aligned} b^{\text{rs}} &= 3/2 \times (23.3 \pm 3.5^{+2.9}_{-3.0}) / ((1156 \pm 112) - 1) \\ &= 0.030 \pm 0.005(\text{stat}) \pm 0.004(\text{syst}). \end{aligned} \quad (7)$$

The  $K_{\pi 2\gamma}$  background estimate did not use the bifurcation method, but used a combination of  $K_{\pi 2}$  events selected in the  $\pi \nu \bar{\nu}(1 + 2)$  data and simulated  $K_{\pi 2}$  and  $K_{\pi 2\gamma}$  events. We simulated both the inner bremsstrahlung (dominant) and direct emission amplitudes of  $K_{\pi 2\gamma}$  decays assuming no interference between them [49]. The  $K_{\pi 2\gamma}$  background was estimated as

$$b^\gamma = \frac{N}{\kappa R_\gamma} \quad (8)$$

where

- (i)  $N = 106$  was the number of  $K_{\pi 2}$ -peak events in the  $\pi \nu \bar{\nu}(1 + 2)$  trigger sample after all selection criteria were applied except that the  $K_{\pi 2}$ -peak region kinematic region was selected.
- (ii)  $\kappa = 417 \pm 24$  was the ratio of acceptance factors of  $K_{\pi 2}$  to  $K_{\pi 2\gamma}$  events as determined from simulated  $K_{\pi 2}$  and  $K_{\pi 2\gamma}$  decays taking into account the  $K_{\pi 2}$  and  $K_{\pi 2\gamma}$  branching ratios. We used  $\mathcal{B}(K^+ \rightarrow \pi^+ \pi^0 \gamma) = (11.1 \pm 0.6) \times 10^{-4}$  obtained by correcting the partial branching ratio  $(2.75 \pm 0.15) \times 10^{-4}$  [24] measured for  $55 < P_\pi < 90$  MeV to the full energy range using simulation.
- (iii)  $R_\gamma = 5.04 \pm 0.10$  was the additional photon veto rejection afforded by the radiative photon. This additional rejection was calculated by combining the distribution of the radiative photon from simulated events with the measured single photon detection efficiency as a function of angle and energy from  $K_{\pi 2}$  data [48].

The final anticipated number of  $K_{\pi 2\gamma}$  background events was  $b^\gamma = 0.076 \pm 0.007 \pm 0.006$ , where the first uncertainty was statistical and the second was systematic (due to  $\kappa$  and  $R_\gamma$ ).

The inverted photon veto used to select events for the  $K_{\pi 2}$  target-scatter normalization branch would have also selected  $K_{\pi 2\gamma}$  events. We corrected the estimate for the  $K_{\pi 2}$  target-scatter background by subtracting  $b^\gamma$ ,

$$b^{\text{tg}} = b_{\text{un}}^{\text{tg}} - b^\gamma = 0.619 \pm 0.150^{+0.067}_{-0.100}. \quad (9)$$

## 2. $K^+ \rightarrow \pi^+ \pi^- e^+ \nu$ background

Despite the small branching ratio of  $(4.09 \pm 0.10) \times 10^{-5}$  [24],  $K_{e4}$  could be a background if the  $\pi^-$  and the  $e^+$  escaped detection in the target. The distribution of the sum of the kinetic energies of the  $\pi^-$  and the  $e^+$  vs the reconstructed  $\pi^+$  momentum in simulated events shown in Fig. 13 indicates where the  $K_{e4}$  background would occur kinematically.

Since the main characteristic of the  $K_{e4}$  event was extra energy in the target from the  $\pi^-$  and the  $e^+$ , the target photon veto (TGPV), OPSVETO and CCDPUL cuts were

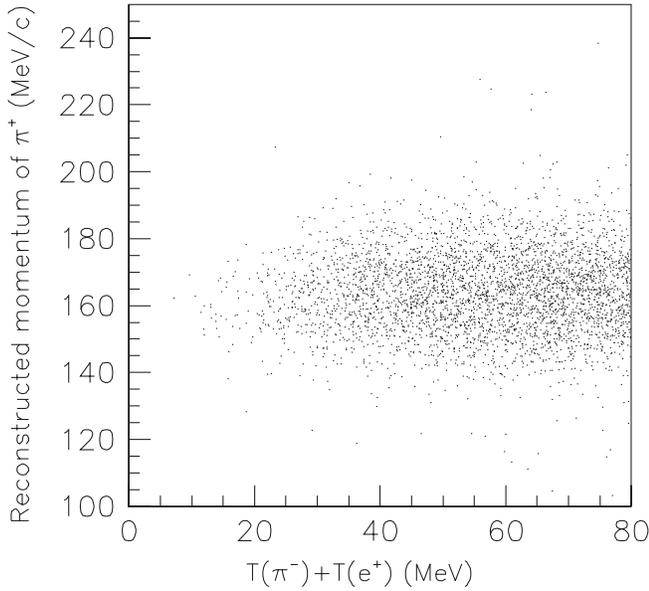

FIG. 13. The sum of the  $\pi^-$  and  $e^+$  kinetic energies vs the reconstructed momentum of the  $\pi^+$  for simulated  $K_{e4}$  events that passed the  $\pi\nu\bar{\nu}(1+2)$  trigger.

the most effective cuts to suppress this background. Because of contamination by other types of background, such as  $K_{\pi 2}$ -target scatter, it was not possible to isolate a pure  $K_{e4}$  background sample for a bifurcation analysis using data only. Nonetheless, a  $K_{e4}$ -rich sample was selected from data using the CCDPUL · TGPV · OPSVETO requirement and served as the normalization branch. We established that the majority of the events in the normalization branch were likely to be due to  $K_{e4}$  decays by removing the CCDPUL requirement and comparing the momentum distribution of the selected events in the 1/3 sample with the expectation from simulation (Fig. 14). In addition, the target information for the 69 events in Fig. 14 was visually examined and the events classified based on the topology, ionization pattern, curvature, range, and energy of the putative tracks. Fifty-nine events were classified as  $K_{e4}$ , three as  $K^+ \rightarrow \pi^+ \mu^- \mu^+$ , and four as  $K_{\pi 2}$  or  $K_{\pi 2\gamma}$  (including events with apparent  $\pi^0 \rightarrow e^+ e^- \gamma$  decays). The classification of the remaining three events was ambiguous. Assuming half the ambiguous events were  $K_{e4}$  yielded a purity of  $\sim 88\%$ . One example of a  $K_{e4}$  candidate event is shown in Fig. 6.

Simulated  $K_{e4}$  events were used to determine the rejection of the TGPV, OPSVETO, and CCDPUL requirements. Negative pion absorption in the target was modeled based on the energy spectrum of stopped  $\pi^-$  in plastic scintillator observed in E787 [50]. We assumed that all energy generated from  $\pi^-$  absorption would be promptly deposited in the single fiber where the  $\pi^-$  came to rest. This assumption conservatively neglected the possibility that detectable activity from  $\pi^-$  absorption could occur

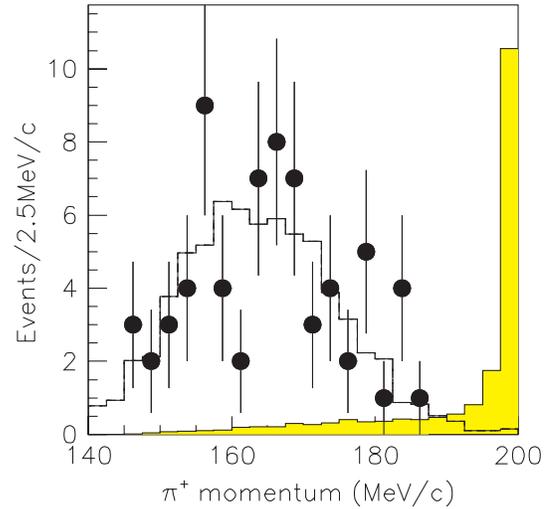

FIG. 14 (color online). Momentum distribution of the  $\pi^+$  in the  $K_{e4}$  normalization branch for the 1/3 sample before the application of the CCDPUL cut. The points represent the data. The unshaded histogram is the distribution as expected from simulated  $K_{e4}$  events. The histogram area is normalized to the number of data events. The shaded histogram represents the normalization branch for  $K_{\pi 2}$  target-scatter events. The ratio of the area of the shaded to the unshaded histogram has been arbitrarily set to 1/8 times the ratio of the  $K_{\pi 2}$  target-scatter background to the  $K_{e4}$  background for display purposes.

elsewhere in the detector.<sup>1</sup> Positron interactions were well modeled in our EGS4-based simulation [46]. The rejection of the CCDPUL, TGPV, and OPSVETO requirements were correlated because the target fibers containing the deposited energy of the  $\pi^-$  and  $e^+$  could have been classified as kaon, pion, photon, or opposite-side pion fibers. We used the energy of the simulated deposits to estimate the rejection of these cuts as  $R = 52_{-29}^{+121}$ . As we did not precisely model either  $\pi^-$  absorption or the inactive material of the target such as the gaps between the fibers and the cladding and wrapping material of each fiber, we varied the threshold for the energy treated by the CCDPUL (TGPV · OPSVETO) cut by a factor of 5 (1.5) to estimate the systematic uncertainty associated with the rejection of these cuts. The normalization branch in the 2/3

<sup>1</sup>Negative pions are predominantly absorbed by carbon nuclei in the scintillator resulting in multinucleon emission. The measured [51,52] rates of emission per stopped  $\pi^-$  of neutrons, protons, deuterons, tritons, and alphas are approximately 2.8, 0.3, 0.2, 0.1, and 0.6, respectively, with typical kinetic energies of tens of MeV. Because of their short range, these charged particles will deposit energy very close to their absorption points. The mean free path of emitted neutrons is tens of centimeters leading to energy deposition relatively far from the absorption point. In addition, the residual nucleus is unstable and can deexcite by emission of photons with typical energies of 1–2 MeV. The energy spectrum measurement [50] was sensitive to energy near the absorption point and thus largely neglected any additional energy deposition due to the latter two processes.

sample contained 6 events so the  $K_{e4}$  background was measured to be  $3/2 \times 6/(52_{-29}^{+121} - 1) = 0.176 \pm 0.072_{-0.124}^{+0.233}$  events, where the first error was statistical and the second was systematic.

### 3. Muon background

The decays  $K^+ \rightarrow \mu^+ \nu_\mu$ ,  $K^+ \rightarrow \mu^+ \nu_\mu \gamma$ , and  $K^+ \rightarrow \mu^+ \pi^0 \nu_\mu$  could contribute background in the  $\pi \nu \bar{\nu}(2)$  kinematic region as indicated in Fig. 4. All three processes required the muon to be misidentified as a pion in order to be a background. The first decay would be background if the kinematics of the  $\mu^+$  were misreconstructed and the latter two decays would be background if the photons went undetected.

The two bifurcation cuts were the  $\pi \rightarrow \mu \rightarrow e$  identification or TD cut (CUT1), and the  $\pi/\mu$  range-momentum separation or RNGMOM (CUT2). The normalization branch defined by inverting the TD cut yielded zero events in the 2/3 sample, so  $N_{\text{norm}}$  was assigned to be 1 event.

The  $\mu^+$  rejection branch contained  $C + D = 20488$  events in the 2/3 sample and was selected by inverting CUT2 and applying cuts to remove beam backgrounds and the  $\pi \nu \bar{\nu}(1)$  version of the photon veto cut (Fig. 10) to suppress  $K_{\pi 2}$  backgrounds. After the application of the TD cut, the number of events remaining was  $C = 154$  for a measured TD cut rejection of  $133.0 \pm 10.7$ . Thus, the  $\mu^+$  background was estimated to be  $3/2 \times (1 \pm 1)/((133.0 \pm 10.7) - 1) = 0.0114 \pm 0.0114$ .

### 4. Charge-exchange background

When the  $K^0$  due to CEX in the target decayed as a  $K_L^0$  it was a potential background. The delayed-coincidence requirement effectively removed any contribution from the short-lived  $K_S^0$ . The semileptonic decay processes  $K_L^0 \rightarrow \pi^+ e^- \bar{\nu}_e$  and  $K_L^0 \rightarrow \pi^+ \mu^- \bar{\nu}_\mu$  with branching ratios of 20% and 14%, respectively, were considered to be the most likely to form a background.

The CEX background could also contain a component due to hyperon production where a  $\pi^+$  was either produced with the hyperon or was a hyperon decay product. Hyperon production would result from  $\bar{K}^0$ -nucleon interactions if the  $K^0$  oscillated to a  $\bar{K}^0$ .

Simulation studies showed that there was often a gap between the pion and kaon fibers and that the reconstructed  $z$  of the pion track was not consistent with the energy deposited in the kaon fibers as indicated schematically in Fig. 15. A CEX-rich sample that served as the normalization branch was selected in  $\pi \nu \bar{\nu}(1 + 2)$  triggers by requiring a gap between the pion and kaon fibers. No target energy cuts were applied in the selection of the normalization sample since the lepton from  $K_L^0$  decay or the  $\pi^-$  and  $\pi^0$  associated with hyperon production might deposit extra energy in the target. The off-line delayed-coincidence requirement was also not applied for the normalization

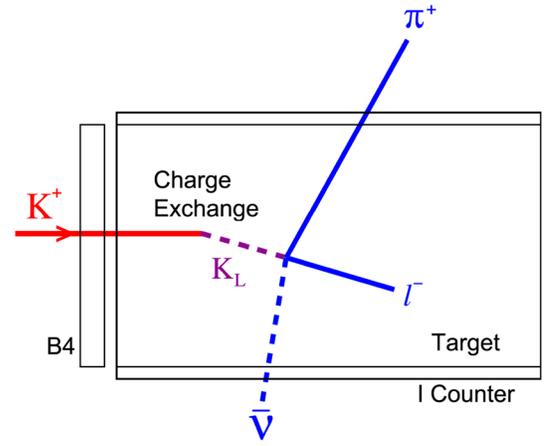

FIG. 15 (color online). Schematic diagram of the charge-exchange process in the target.

sample. In contrast to the previous  $\pi \nu \bar{\nu}(2)$  analysis [45], the ability to create a normalization sample from  $\pi \nu \bar{\nu}(1 + 2)$  data avoided uncertainties associated with the effective CEX cross section and related efficiencies. In addition a normalization sample selected from the data contains contributions from all CEX processes including  $K_L^0$  and hyperon decays. The normalization branch in the 2/3 sample contained one event.

The rejection associated with finding a gap in the CEX events, the target energy cuts, and the delayed coincidence was determined from simulated CEX  $K_L^0 \rightarrow \pi^+ \ell^- \bar{\nu}$  events. For the simulation of CEX events, reconstructed  $K_S^0 \rightarrow \pi^+ \pi^-$  events obtained from the CEX monitor trigger data (Sec. II B) were used as the  $K_L^0$  production point and momentum. The rejection of the delayed coincidence and gap-finding cuts exploit the flight of the neutral kaon and should be the same for  $K_L^0 \rightarrow \pi^+ \ell^- \bar{\nu}$  and hyperons. The rejection of the target energy cuts on the  $\pi^-$  or  $\pi^0$  associated with hyperon decay was estimated to be comparable to or greater than the rejection of the target energy cuts on the lepton from  $K_L^0 \rightarrow \pi^+ \ell^- \bar{\nu}$  decays. The background was measured in the 2/3 sample to be  $0.013 \pm 0.013(\text{stat})_{-0.003}^{+0.010}(\text{syst})$  events. The systematic uncertainty was estimated by the same threshold variations of the target energy cuts that were used for  $K_{e4}$  (Sec. III C 2).

### 5. Single-beam background

The bifurcation cuts for single-beam background were the delayed coincidence (CUT1) and B4 energy of less than 1.0 MeV (CUT2). CUT2 selected beam pions. The sample was selected by applying all the photon veto cuts except TGPV, the kinematic cuts, TD cuts, and beam cuts except the delayed coincidence and CUT2. The normalization sample formed by the inversion of the delayed-coincidence cut samples yielded zero events, so that  $N_{\text{norm}}$  was assigned to be 1. The rejection sample contained  $C + D = 12850$  events in the 2/3 data. After the applica-

tion of the delayed coincidence,  $C = 2$  events remained for a rejection of the delayed-coincidence cut of  $6425 \pm 4543$ . The measured single-beam background was  $3/2 \times (1 \pm 1)/(6425 - 1) = 0.00023 \pm 0.00023$  events.

### 6. Double-beam background

Double-beam background had two components,  $KK$  and  $K\pi$ . For the  $KK$  ( $K\pi$ ) background, the decay products of the initial kaon were undetected and a subsequent kaon decay (a scattered beam pion) provided the outgoing  $\pi^+$ .

The  $KK$  component of the background  $b^{KK}$  was determined using the bifurcation procedure described in Sec. III A 3 with modifications to compensate for poor statistics:

$$b^{KK} = f \times \frac{n_{KK}/r_{KK}}{R_{KK} - 1} \quad (10)$$

where  $f = 3/2$  was the scale factor for the  $2/3$  data sample [Eq. (3)].

- (i)  $R_{KK} = 1576/4 = 394 \pm 197$  was the measured rejection of the kaon Čerenkov and BWPC cuts (CUT1) on a beam kaon at the time of the outgoing pion ( $t_{rs}$ ). The rejection sample was prepared by vetoing beam pions at  $t_{rs}$  via Čerenkov information, by requiring a second track at  $t_{rs}$  in the B4 counter with an energy deposit consistent with a kaon, and by the more stringent target gap requirement described in Sec. III B 2. The latter criterion ensured activity in the target in two spatially and temporally distinct regions indicative of a double-beam event.
- (ii)  $\frac{n_{KK}}{r_{KK}}$  was the normalization provided by a second bifurcation of the standard normalization branch. The second bifurcation [2] exploited the lack of correlation between the AD and target cuts to improve the statistical power of the measurement. The normalization branch was prepared by inverting CUT1, by vetoing entering pions at  $t_{rs}$  using Čerenkov information, and by application of the  $\pi \rightarrow \mu \rightarrow e$  and track quality requirements on the outgoing track and contained 2699 events. The application of the AD photon veto cuts reduced the sample to 325 events for a rejection of  $r_{KK} = 8.3 \pm 0.4$ . The application of the target cuts on the 2699 events yielded zero events so we assigned  $n_{KK} = 1$ . These values gave the  $KK$  background of  $b^{KK} = 0.00046 \pm 0.00046$  events.

An analogous method was used to estimate the  $K\pi$  component of the double-beam background

$$b^{K\pi} = \frac{1}{1 - 0.606} \times f \times \frac{n_{K\pi}/r_{K\pi}}{R_{K\pi} - 1} \quad (11)$$

where the additional scale factor of  $1/(1-0.606)$  was included to correct for the data accumulated with the online pion Čerenkov veto in the  $\pi\nu\bar{\nu}(2)$  trigger (Sec. II B). With the online veto, the off-line rejection of the pion Čerenkov

cuts was low and the normalization branch lacked statistics. To obtain  $b^{K\pi}$ , the  $K\pi$  background estimate obtained without the on-line veto was scaled by the ratio of the kaon exposures. As a check of this scaling, we verified that the  $KK$  background estimates for the two trigger configurations were consistent and that the  $K\pi$  background for the  $\pi\nu\bar{\nu}(1)$  trigger data was consistent for the two data-taking periods [53]. With the measured values of  $R_{K\pi} = 2467/4 = 617 \pm 308$ ,  $n_{K\pi} = 1 \pm 1$ , and  $r_{K\pi} = 4435/464 = 9.6 \pm 0.4$  in Eq. (11), we obtained  $b^{K\pi} = 0.00064 \pm 0.00064$  events.

### 7. Background summary

The contribution of each background component is listed in Table II. The total background was estimated to be  $0.927 \pm 0.168^{+0.320}_{-0.237}$  events and was dominated by the  $K_{\pi 2}$  target-scatter component that was the largest contribution to the statistical uncertainty. The systematic uncertainty was dominated by the contribution from the  $K_{e4}$  background due to the inability to establish a precise correspondence between the energy observed in the target in data and simulation.

A number of background consistency and validity checks were performed as described below.

### 8. Background contamination evaluation

Because of the difficulty of isolating background samples, studies were performed to estimate the degree of contamination (i.e., events due to background from other sources) in the  $K_{\pi 2}$  target-scatter normalization and rejection branches (Fig. 12).

The effect of muon contamination of the  $K_{\pi 2}$  background estimate was determined separately for the normalization and rejection branches with and without the  $\pi \rightarrow \mu \rightarrow e$  (TD) and  $\pi/\mu$  range-momentum separation (RNGMOM) cuts. The normalization branch used in the  $K_{\pi 2}$ -scatter study was assumed to be the sum of  $\pi^+$  and  $\mu^+$  components such that

$$N_{\text{norm}} = 1131 = N_{\text{norm}}^{\pi} + N_{\text{norm}}^{\mu}. \quad (12)$$

TABLE II. Summary of the estimated number of events in the signal region from each background component. Each component is described in the text.

Process	Background events
$K_{\pi 2}$ target scatter	$0.619 \pm 0.150^{+0.067}_{-0.100}$
$K_{\pi 2}$ range-stack scatter	$0.030 \pm 0.005 \pm 0.004$
$K_{\pi 2\gamma}$	$0.076 \pm 0.007 \pm 0.006$
$K_{e4}$	$0.176 \pm 0.072^{+0.233}_{-0.124}$
Muon	$0.011 \pm 0.011$
Charge exchange	$0.013 \pm 0.013^{+0.010}_{-0.003}$
Beam	$0.001 \pm 0.001$
Total	$0.927 \pm 0.168^{+0.320}_{-0.237}$

When the TD and RNGMOM cuts were not applied, the observed number of events in the normalization branch was

$$n = 12980 = N_{\text{norm}}^\pi / A_\pi + R_\mu N_{\text{norm}}^\mu, \quad (13)$$

where  $A_\pi$  ( $R_\mu$ ) is the acceptance (rejection) factor for the combination of the TD and RNGMOM cuts for pions (muons). The rejection of the TD cut was evaluated as  $133.0 \pm 10.7$  as part of the muon background estimate (Sec. III C 3). The RNGMOM rejection of  $28.3 \pm 1.1$  was evaluated using the muon normalization branch for a total muon rejection of  $R_\mu = 3764 \pm 333$ . The acceptance factor  $A_\pi$  of the combination of the TD and RNGMOM cuts was determined on samples of  $K_{\pi 2}$ -peak region events that failed different combinations of the target-scatter cuts used to assess the uncertainty in the photon veto rejection as described in Sec. III B 7. The acceptance factors for these samples, both before and after the application of the standard photon veto cut, were consistent and yielded  $A_\pi = 0.809 \pm 0.030$ . These gave the muon contamination of the normalization sample of  $N_{\text{norm}}^\mu / N_{\text{norm}} = (2.7 \pm 0.3) \times 10^{-3}$ . Analogous methodology was used to assess the effect of muon contamination in the rejection branch. The calculated photon veto rejection after correction for muon contamination was  $R^\pi = 2410 \pm 518$  to be compared with  $R = 2392 \pm 510$  (Sec. III C 1). Inserting these results into the background estimate using the bifurcation method [Eq. (3)] implied that the muon contamination increased the  $K_{\pi 2}$  background ( $b$ ) estimate by

$$b/b^\pi = f \frac{N_{\text{norm}}}{R-1} / f \frac{N_{\text{norm}}^\pi}{R^\pi-1} = 1.010 \pm 0.002$$

which was considered negligible with respect to the estimated systematic uncertainty.

A similar treatment limited the overestimate of the  $K_{\pi 2}$  background due to double-beam contamination to be  $<0.1\%$ .

The rejection of  $K_{e4}$  by the photon veto should be less than the photon veto rejection of  $K_{\pi 2}$  and  $K_{\pi 2\gamma}$  in that there were no photons in the final state. Contamination of the  $K_{\pi 2}$  rejection sample by  $K_{e4}$  events would therefore reduce the measured photon veto rejection. The measured rejection of  $39481/18 = 2193 \pm 517$  in the tighter kinematic region, that was defined to suppress  $K_{e4}$  (Sec. III B 4), was consistent with the overall rejection of  $2392 \pm 510$  (Sec. III C 1), indicating no significant contamination of the  $K_{\pi 2}$  rejection sample by  $K_{e4}$ . The  $K_{\pi 2}$  normalization branch was defined by the inversion of the photon veto cuts and the application of the target-quality cuts, including CCDPUL and OPSVETO. The  $K_{e4}$  normalization was prepared by application of CCDPUL · TGPV · OPSVETO. Since TGPV · OPSVETO · CCDPUL was a subset of the  $K_{\pi 2}$  normalization branch,

the contamination of the  $K_{\pi 2}$  normalization branch by  $K_{e4}$  was less than the six events selected in the  $K_{e4}$  normalization branch (Sec. III C 2) and hence negligible compared to the 1131 events in the  $K_{\pi 2}$  normalization branch [Eq. (5)].

### 9. Background consistency checks

The consistency of the background estimate was checked in three distinct data regions just outside the signal region that were created by loosening the photon veto cut and the CCDPUL cut. The region CCD<sub>1</sub> was immediately adjacent to the signal region and contained events with a CCDPUL second-pulse energy above the standard threshold of 1.25 MeV and below 2.5 MeV. The region PV<sub>1</sub> was immediately adjacent to the signal region and defined by events rejected by the standard photon veto and accepted by the loose photon veto cuts (Fig. 10). The region PV<sub>2</sub> was adjacent to PV<sub>1</sub> and defined by events rejected by the loose photon veto and accepted by the  $\pi\nu\bar{\nu}(1)$  photon veto cuts (Fig. 10). The numbers of expected background events in these regions were calculated in the same manner as for the signal region.

Table III shows the number of expected and observed events in the three regions as well as the probability of the observed number of events or fewer given the expectation. The combined probability of 5% for the two regions nearest the signal region may have indicated that the background was overestimated, but the reevaluation of this combined probability at the lower limit of the systematic uncertainties [54] gave 14% for the two closest regions which demonstrated that the assigned systematic uncertainties were reasonable.

The assignment of  $N_{\text{norm}} = 1$  when no events were observed in the normalization branch (Sec. III A 3) was only made for the muon, single-beam, and  $KK$  double-beam backgrounds. Thus, this assignment could have overestimated the total background by, at most, 0.012 events or 1.3%.

TABLE III. Comparison of the expected ( $N_E$ ) and observed ( $N_O$ ) number of background events in the three regions CCD<sub>1</sub>, PV<sub>1</sub>, and PV<sub>2</sub> outside the signal region. The central value of  $N_E$  is given along with the combined statistical and systematic uncertainties.  $\mathcal{P}(N_O; N_E)$  is the probability of observing  $N_O$  or fewer events when  $N_E$  events are expected. The rightmost column “Combined” gives the probability of the combined observation in that region and the region(s) of the preceding row(s). The numbers in square brackets are the probabilities reevaluated at the upper and lower bounds of the uncertainty on  $N_E$  [54].

Region	$N_E$	$N_O$	$\mathcal{P}(N_O; N_E)$	Combined
CCD <sub>1</sub>	$0.79^{+0.46}_{-0.51}$	0	0.45 [0.29,0.62]	
PV <sub>1</sub>	$9.09^{+1.53}_{-1.32}$	3	0.02 [0.01,0.05]	0.05 [0.02,0.14]
PV <sub>2</sub>	$32.4^{+12.3}_{-8.1}$	34	0.61 [0.05,0.98]	0.14 [0.01,0.40]

### D. Acceptance and sensitivity

We assessed the overall acceptance of all selection criteria by dividing the criteria into components that could be measured separately using monitor triggers or simulated data. Simulated data were used to estimate the acceptance of the trigger and decay phase space as well as to assess the impact of nuclear interactions. The overall acceptance was the product of the acceptance factors for each component. Correlated cuts were grouped together for evaluation.

#### 1. Acceptance factors from $K_{\mu 2}$ events

$K_{\mu 2}$  monitor triggers were used to assess the components of the acceptance regarding the kaon beam, the charged track, the event topology, and the standard photon veto. The acceptance factors are listed in Table IV and described below.

To measure the acceptance of the range-stack track reconstruction, a sample of  $K_{\mu 2}$  monitor triggers was selected by requiring a good track in the target and UTC, an energy deposit in the B4 hodoscope consistent with a beam kaon, and a delayed coincidence of  $>5$  ns based on  $C_K$  and the IC.

The acceptance associated with the matching of the range stack and UTC track was assessed using a  $K_{\mu 2}$  sample with a good track in the range stack, a delayed coincidence of  $>5$  ns based on the  $\check{C}_K$  and the IC, and a single entering kaon selected based on the B4 energy deposit and the beam Čerenkov and wire chambers.

The acceptance factor associated with the beam and target pattern recognition was evaluated on a sample of  $K_{\mu 2}$  events that were required to have a single entering kaon and a good track in the UTC and range stack with  $|\cos\theta| < 0.5$ . In addition the momentum of the reconstructed track was required to be within 2 standard deviations of the expectation for  $K_{\mu 2}$  decays. There were over 40 individual cuts associated with the beam and target pattern recognition as described in Sec. III B 2. The majority of the individual cuts had acceptance greater than 90% except for the delayed-coincidence (75.5%) and the CCDPUL (45.1%) requirements.

To measure the acceptance of the standard photon veto, an additional criterion was applied to the  $K_{\mu 2}$  events used

TABLE IV. Acceptance factors of the  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  selection criteria measured with  $K_{\mu 2}$  monitor trigger data. Only statistical uncertainties are shown. The product is  $A_{K_{\mu 2}}$ .

Cut	Acceptance factor
Range-stack track reconstruction	$0.999\,93 \pm 0.000\,01$
UTC-range-stack track matching	$0.999\,43 \pm 0.000\,02$
Beam and target pattern	$0.150\,81 \pm 0.000\,18$
Photon veto	$0.481\,22 \pm 0.002\,00$
$A_{K_{\mu 2}}$	$0.072\,53 \pm 0.000\,31$

for the beam and target acceptance. As muons from  $K_{\mu 2}$  decay can penetrate into the barrel veto liner, the reconstructed track was required to stop before the outermost layer of the range stack. The acceptance factor given in Table IV evaluated in this manner yielded the overall acceptance of both the on-line and off-line photon veto cuts as the  $K_{\mu 2}$  monitor trigger did not include the photon veto.

#### 2. Acceptance factors from $K_{\pi 2}$ events

The  $K_{\pi 2}$  monitor data were used to assess the acceptance factors associated with charged-track reconstruction in the UTC and in the target. The acceptance of the veto of an additional track in the target (OPSVETO, Sec. III B 2) was also measured with  $K_{\pi 2}$  monitors. The factors are listed in Table V and described below.

To measure the acceptance of the UTC reconstruction, events from the  $K_{\pi 2}$  monitor trigger were required to have a well-reconstructed track in the range stack and agreement between the on-line and off-line determination of the range-stack stopping counter.

For the measurement of the acceptance of the OPSVETO cut, in addition to the requirements described above, the charged track was required to be well reconstructed in the UTC and range stack, identified as a  $\pi^+$  from  $K_{\pi 2}$  decay based on the measured range and momentum as well as the  $\pi \rightarrow \mu \rightarrow e$  signature in the stopping counter and kinematically consistent with the pion from a  $K_{\pi 2}$  decay. Cuts were also applied to ensure a single kaon entered the target.

In addition to the requirements described above, the OPSVETO and target photon veto cuts were applied to the  $K_{\pi 2}$  monitor events to assess the cumulative acceptance of the ten cuts associated with target-track reconstruction. These ten cuts were designed to reject tracks that contained an indication of a kink or discontinuity in the pattern of target fibers or target fibers with an unexpected energy deposit (Sec. III B 2). Two individual cuts with less than 90% acceptance were the requirement that no individual pion fiber had more than 3 MeV (89.6%) and the requirement on the target-track fitter probability  $\mathcal{P}(\chi_5^2 + \chi_6^2 + \chi_7^2)$  (87.4%).

TABLE V. Acceptance factors measured with  $K_{\pi 2}$  monitor trigger data. Uncertainties are statistical only. The product of all factors is  $A_{K_{\pi 2}}$ .

Cut	Acceptance factor
UTC reconstruction	$0.943\,45 \pm 0.000\,19$
OPSVETO	$0.974\,17 \pm 0.000\,63$
Target-track reconstruction	$0.718\,51 \pm 0.001\,81$
$A_{K_{\pi 2}}$	$0.6604 \pm 0.0018$

### 3. Acceptance factors from $\pi_{\text{scat}}$ events

Beam pions that scatter in the target had range, energy, and momentum spectra similar to that of pions from  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  and were used to determine the acceptance factors associated with the reconstruction and identification of pions in the range stack. Table VI lists the acceptance factors measured using  $\pi_{\text{scat}}$  monitors.

Candidate events were only accepted if the pion stopped in a counter with an operational TD (“good TD”). The acceptance factor associated with this requirement was measured on a sample of  $\pi_{\text{scat}}$  monitor data selected by requiring a single pion entering the target, a good outgoing track in the target, UTC and range stack, a delayed coincidence of less than 5 ns, and range, energy, and momentum in the signal region.

In addition to the requirements listed above,  $\pi_{\text{scat}}$  monitor data were also required to have a good  $\pi \rightarrow \mu \rightarrow e$  signature and the pion was required to stop in a range-stack counter with an operational TD in order to measure the acceptance factor associated with the range-stack kinematics and tracking. Assignment of target fibers to the incoming and outgoing pions in  $\pi_{\text{scat}}$  was not as robust as the assignments made for kaon decays at rest. Misassignment of target fibers yielded a larger uncertainty in the momentum, range, and energy calculated for the outgoing pion in  $\pi_{\text{scat}}$  events. The effect of increasing or decreasing the signal region in momentum, range, and energy (Sec. III B 4) by  $\pm 1$  standard deviation was used to estimate the systematic uncertainty in this acceptance factor.

The requirements used to assess the acceptance factor associated with a nonoperational TD in the stopping counter were supplemented by requiring a good track in the UTC and application of the RNGMOM cut in order to measure the acceptance factor associated with the  $\pi \rightarrow \mu \rightarrow e$  signature. The cut on the measured  $dE/dx$  in range-stack counters and the cuts on the consistency of the range stack and UTC track were slightly correlated with the suite of cuts used to define the  $\pi \rightarrow \mu \rightarrow e$  signature [55]. The acceptance factor of the  $\pi \rightarrow \mu \rightarrow e$  signature was assessed both with and without these cuts applied to estimate the systematic uncertainty due to these correlations. In addition, a relative correction of +1.4% for pion decay

TABLE VI. Acceptance factors measured with  $\pi_{\text{scat}}$  monitor triggers. The first and second uncertainties are statistical and systematic, respectively. The assessment of systematic uncertainties is described in the text.  $A_{\pi_{\text{scat}}}$  is the product of the three acceptance factors.

Cut	Acceptance factor
Good TD in stopping counter	$0.9984 \pm 0.0001$
Range-stack kinematics	$0.8259 \pm 0.0013 \pm 0.0120$
$\pi \rightarrow \mu \rightarrow e$ signature	$0.4805 \pm 0.0015 \pm 0.0160$
$A_{\pi_{\text{scat}}}$	$0.3980 \pm 0.0014 \pm 0.0140$

in flight and pion absorption in the stopping counter, estimated from simulation, was applied to the acceptance factor associated with the  $\pi \rightarrow \mu \rightarrow e$  signature.

### 4. Acceptance factors from simulated events

Simulated  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  events were used to evaluate the acceptance factors associated with the trigger, phase space, and  $\pi^+$ -nuclear interactions in the detector. The acceptance of the L1.1 and L1.2 (DC) components of the trigger as described in Sec. II B were evaluated with  $K_{\pi 2}$  ( $K_{\mu 2}$ ) monitors as described previously in this section. The acceptance of the remaining trigger components is given in the second row of Table VII. The phase space acceptance includes the loss due to  $\pi^+$  absorption in the stopping counter and decay in flight. Aside from  $\pi^+$  absorption in the stopping counter, neither the trigger nor the phase space acceptance include the effect of nuclear interactions. As indicated in Sec. III A, the combined trigger and phase space acceptance factor of 11.8% ( $= 0.3225 \times 0.3650$ ) was larger than the corresponding factor of 6.5% for the  $\pi \nu \bar{\nu}(1)$  region [2]. The acceptance factor associated with  $\pi^+$ -nuclear interactions was evaluated separately and is given in the fourth row of Table VII. For the  $\pi \nu \bar{\nu}(1)$  region, the acceptance factor due to nuclear interactions was 49.5% [2].

### 5. Correction to the $T \cdot 2 \cdot IC$ efficiency

The  $T \cdot 2 \cdot IC$  component of the trigger (Sec. II B) required a coincidence between range-stack counters in the same sector in the two innermost layers and in the IC. The simulation did not include the acceptance loss due to gaps between the neighboring  $T$  counters or due to insufficient scintillation light in the thin  $T$  counters. These acceptance losses were measured by using  $K_{\mu 2}$  and  $K_{\pi 2}$  decays in KB monitor events. The energy loss in the  $T$  counter by the charged track differs for  $K_{\mu 2}$  and  $K_{\pi 2}$  events and simulated events were used to obtain the average energy loss for each decay. The measured acceptance factors for  $K_{\mu 2}$  and  $K_{\pi 2}$  were then extrapolated to estimate

$$A_{T \cdot 2 \cdot IC} = 0.9505 \pm 0.0012 \pm 0.0143 \quad (14)$$

where a  $\pm 1.5\%$  systematic uncertainty was assigned to

TABLE VII. Acceptance factors determined from simulated  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  decays.  $A_{MC}$  is the product of the three acceptance factors. The uncertainties are statistical.

Component	Acceptance factor
Trigger	$0.3225 \pm 0.0015$
Phase space	$0.3650 \pm 0.0027$
$\pi^+$ -nuclear interactions	$0.8284 \pm 0.0104$
$A_{MC}$	$0.0975 \pm 0.0009$

account for the extrapolation of the UTC track to the  $T$  counter.

### 6. Normalization to the $K_{\mu 2}$ branching ratio

We assessed the fraction ( $f_s$ ) of  $K^+$  that stopped in the target by normalization to the  $K_{\mu 2}$  branching ratio [24] as described in [2]

$$f_s = 0.7740 \pm 0.0011. \quad (15)$$

### 7. Confirmation of the $K_{\pi 2}$ branching ratio

The  $K_{\pi 2}$  branching ratio was measured using the  $K_{\pi 2}$  monitor trigger data in order to confirm the validity of the majority of acceptance factors and corrections calculated with data and simulation. The acceptance factors associated with the photon veto (Table IV) were not checked by this procedure because the standard photon veto cuts were not applied for this measurement. Our measurement followed the same analysis procedure as described in [2] but utilized the selection criteria developed for the  $\pi\nu\bar{\nu}(2)$  analysis. From this analysis we obtained

$$\mathcal{B}(K^+ \rightarrow \pi^+ \pi^0) = 0.221 \pm 0.002 \quad (16)$$

where the uncertainty is statistical. The 6% difference with the world average value [24] of  $0.209 \pm 0.001$  for the branching ratio was taken into account in the assigned systematic uncertainty discussed in the next section.

### 8. Overall acceptance and sensitivity

The total acceptance was evaluated as the product of  $A_{K_{\pi 2}}$ ,  $A_{K_{\mu 2}}$ ,  $A_{\pi_{\text{scat}}}$ ,  $A_{\text{MC}}$ ,  $f_s$ , and  $A_{T \cdot 2 \cdot IC}$  giving  $A_{\text{tot}} = (1.37 \pm 0.14) \times 10^{-3}$  where we assigned a 10% uncertainty on the total acceptance to accommodate the discrepancy in  $\mathcal{B}(K^+ \rightarrow \pi^+ \pi^0)$  and the additional systematic and statistical uncertainties in the acceptance evaluated in this section. Based on the total exposure of  $N_K = 1.71 \times 10^{12}$  stopped kaons for this analysis, the single event sensitivity [ $\text{SES} \equiv 1/(N_K A_{\text{tot}})$ ] of the  $\pi\nu\bar{\nu}(2)$  analysis was  $\text{SES} = (4.28 \pm 0.43) \times 10^{-10}$  which can be compared with the SES of the E949  $\pi\nu\bar{\nu}(1)$  analysis of  $(2.55 \pm 0.20) \times 10^{-10}$  [2] and the combined SES of the previous  $\pi\nu\bar{\nu}(2)$  analyses of  $(6.87 \pm 0.04) \times 10^{-10}$  [35,45].

### E. Likelihood method

We determined  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu\bar{\nu})$  using a likelihood method that took into account the distributions of the predicted background and acceptance within the signal region. The signal region was divided into nine cells with differing acceptance-to-background ratios as described below. The likelihood ratio  $X$  was defined as

$$X \equiv \prod_{i=1}^n \frac{e^{-(s_i+b_i)}(s_i+b_i)^{d_i}}{d_i!} \bigg/ \frac{e^{-b_i} b_i^{d_i}}{d_i!} \quad (17)$$

TABLE VIII. The estimated signal-to-background ( $s/b$ ) and background ( $b$ ) for the nine signal region cells. The cuts defining each cell are also given. The  $s/b$  is calculated assuming  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu\bar{\nu}) = 1.73 \times 10^{-10}$ . The uncertainties on  $b$  and  $s/b$  are omitted from the table. In the definition column,  $\text{KIN}_S$  indicates the region defined by the standard decay pion kinematics cut and  $\text{KIN}_T$  indicates the region defined by the tight version of the kinematics cut.  $\text{KIN}_R$  is defined as  $\text{KIN}_S \equiv \text{KIN}_T + \text{KIN}_R$ . Analogous designations are used for the photon veto (PV), delayed coincidence, (DC) and  $\pi \rightarrow \mu \rightarrow e$  (TD) cuts.

Cell	Definition	$b$	$s/b$
1	$\text{KIN}_T \cdot \text{TD}_T \cdot \text{DC}_T \cdot \text{PV}_T$	0.152	0.84
2	$\text{KIN}_T \cdot \text{TD}_R \cdot \text{DC}_T \cdot \text{PV}_T$	0.038	0.78
3	$\text{KIN}_T \cdot \text{TD}_T \cdot \text{DC}_R \cdot \text{PV}_T$	0.019	0.66
4	$\text{KIN}_T \cdot \text{TD}_R \cdot \text{DC}_R \cdot \text{PV}_T$	0.005	0.57
5	$\text{KIN}_T \cdot \text{TD}_T \cdot \text{DC}_T \cdot \text{PV}_R$	0.243	0.47
6	$\text{KIN}_T \cdot \text{TD}_R \cdot \text{DC}_T \cdot \text{PV}_R$	0.059	0.45
7	$\text{KIN}_T \cdot \text{TD}_T \cdot \text{DC}_R \cdot \text{PV}_R$	0.027	0.42
8	$\text{KIN}_T \cdot \text{TD}_R \cdot \text{DC}_R \cdot \text{PV}_R$	0.007	0.35
9	$\text{KIN}_R \cdot \text{TD}_S \cdot \text{DC}_S \cdot \text{PV}_S$	0.379	0.20

where  $s_i$  and  $b_i$  were the estimated signal and background in the  $i$ th cell, respectively,  $d_i$  was the observed number of signal candidates in the  $i$ th cell, and  $n$  was the total number of cells [56]. The estimated signal in each cell was given by  $s_i \equiv \mathcal{B}(K^+ \rightarrow \pi^+ \nu\bar{\nu})/\text{SES}_i$ , where  $\text{SES}_i$  was the single event sensitivity of the  $i$ th cell.

The division of the signal region into nine cells was performed using combinations of the decay pion kinematics (KIN), PV, DC or  $\pi \rightarrow \mu \rightarrow e$  (TD) cuts. We defined a standard (e.g.,  $\text{KIN}_S$ ) and a more restrictive or tight version of each cut as described previously in Secs. III B 4 ( $\text{KIN}_T$ ), III B 7 ( $\text{PV}_T$ ), III B 6 ( $\text{DC}_T$ ) and III B 5 ( $\text{TD}_T$ ), and  $\text{KIN}_R$  was defined as  $\text{KIN}_S \equiv \text{KIN}_T + \text{KIN}_R$ . The signal region was defined by the application of the standard version of all cuts. The signal region was then subdivided into cells by the additional selective application of the tight version of each cut or the inverted cut as shown in Table VIII.

The additional signal acceptance factor and rejection (Table IX) for each of the four tight cuts was determined using analogous techniques and samples as described in Secs. III D and III C respectively. Based on studies of data and simulated events, the background components for

TABLE IX. Additional acceptance factor ( $A$ ) or rejection ( $R$ ) for the tight version of the  $\text{KIN}_T$ ,  $\text{PV}_T$ ,  $\text{DC}_T$ , and  $\text{TD}_T$  cuts for specific backgrounds.

	$\text{KIN}_T$	$\text{TD}_T$	$\text{DC}_T$	$\text{PV}_T$
$A$	0.812	0.812	0.911	0.522
$R$	1.63( $K_{\pi 2}$ )	3.08 (muon)	6.3 (CEX)	2.75( $K_{\pi 2}$ )
	2.70( $K_{e 4}$ )		1.0 (beam)	2.75( $K_{\pi 2\gamma}$ )
	1.20( $K_{\pi 2\gamma}$ )			

which no rejection is given in the table were reduced by the acceptance factor of the particular cut. For example, the acceptance of the cell defined by  $\text{KIN}_T \cdot \text{TD}_R \cdot \text{DC}_R \cdot \text{PV}_T$  relative to the acceptance for the entire signal region was  $A_{\text{KIN}_T} \times (1 - A_{\text{TD}_T}) \times (1 - A_{\text{DC}_T}) \times A_{\text{PV}_T}$  with obvious notation, and the  $K_{\pi 2}$ -target-scatter background component relative to the contribution to the entire signal region was reduced by the factor  $1/R_{\text{KIN}_T} \times (1 - A_{\text{TD}_T}) \times (1 - A_{\text{DC}_T}) \times 1/R_{\text{PV}_T}$ .

#### IV. RESULTS

In this section, we describe the results of examining the signal region and the evaluation of the  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  branching ratio. We also describe the evaluation of our observations within alternative models of  $K^+ \rightarrow \pi^+ + \text{nothing}$ .

##### A. Examination of the signal region

After completion of the background and acceptance analyses, all selection criteria were applied to the  $\pi \nu \bar{\nu}(1 + 2)$  trigger data. Three signal candidate events were observed. Some measured properties of the three events are listed in Table X. The plot of the kinetic energy vs range of the three events along with the events found in the previous  $\pi \nu \bar{\nu}(1)$  [2] and  $\pi \nu \bar{\nu}(2)$  [35,45] analyses are shown in Fig. 16. The candidates' measured properties used in the selection criteria were consistent with the expected distributions for  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  decay signal. There was no observed activity in the kaon fibers at the time of the  $\pi^+$  for any of the three candidates according to the CCDPUL analysis. All three events failed one or more of the tight cuts described in Sec. III E. The  $\pi^+$  momentum of event A failed the tight momentum cut of 165 MeV/c. Events B and C failed the tight photon veto cut due to energy deposits of 2.4 and 2.1 MeV in the EC above the 1.7 MeV threshold, respectively, and events A and C failed the tight  $\text{DC}_T$  cut of 6 ns on the kaon-decay time.

TABLE X. The cell (Table VIII) and the momentum, range, and energy of the  $\pi^+$  in the three signal candidate events A, B, and C. The measured decay times are in units of  $K^+$ ,  $\pi^+$ , and  $\mu^+$  lifetimes [24], appropriately.

Event	A	B	C
Cell	9	5	7
Momentum (MeV/c)	161.5	188.4	191.3
Range (cm)	17.3	24.2	26.1
Kinetic energy (MeV)	76.1	95.6	97.9
$K^+$ decay time	0.30	1.27	0.42
$\pi^+$ decay time	0.86	0.64	0.39
$\mu^+$ decay time	2.71	1.03	4.33

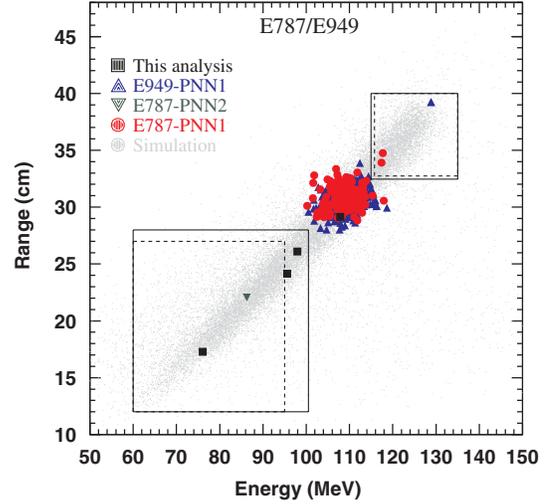

FIG. 16 (color online). Kinetic energy vs range of all events passing all other cuts. The squares represent the events observed by this analysis. The circles and upward-pointing triangles represent the events observed by the E787 and E949  $\pi \nu \bar{\nu}(1)$  analyses, respectively. The downward-pointing triangles represent the events observed by the E787  $\pi \nu \bar{\nu}(2)$  analyses. The solid (dashed) lines represent the limits of the  $\pi \nu \bar{\nu}(1)$  and  $\pi \nu \bar{\nu}(2)$  signal regions for the E949 (E787) analyses. Despite the smaller signal region in  $R_\pi$  vs  $E_\pi$ , the  $\pi \nu \bar{\nu}(1)$  analyses were 4.2 times more sensitive than the  $\pi \nu \bar{\nu}(2)$  analyses. The points near  $E_\pi = 108$  MeV were  $K_{\pi 2}$  decays that survived the photon veto cuts and were predominantly from the  $\pi \nu \bar{\nu}(1)$  analyses due to the higher sensitivity and the less stringent photon veto cuts. The light gray points are simulated  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  events that were accepted by the  $\pi \nu \bar{\nu}(1 + 2)$  trigger.

##### B. The $K^+ \rightarrow \pi^+ \nu \bar{\nu}$ branching ratio

The central value of the  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  branching ratio was taken to be the value of  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu})$  that maximized the likelihood ratio  $X$  [Eq. (17)]. For the three events observed by this analysis, we determined  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) = (7.89_{-5.10}^{+9.26}) \times 10^{-10}$  where the quoted 68% confidence level interval was determined from the behavior of  $X$  as described in [56] and took into account both the statistical and systematic uncertainties. The systematic uncertainties included the 10% uncertainty in the acceptance as well as the uncertainties in the estimation of the background components. The inclusion of systematic uncertainties had a negligible effect on the confidence level interval due to the poor statistical precision inherent in a three event sample. The probability that these three events were due to background only, given the estimated background in each cell (Table VIII), was 0.037.

When the results of the previous  $\pi \nu \bar{\nu}(1)$  and  $\pi \nu \bar{\nu}(2)$  analyses [2,35,45] were combined with the results of this analysis, we determined  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) = (1.73_{-1.05}^{+1.15}) \times 10^{-10}$  [57]. Systematic uncertainties were treated as described above when performing the combination, except that we assumed a correlated 10% uncertainty for the

TABLE XI. The measured branching ratios in units of  $10^{-10}$  assuming a standard model, scalar, or tensor interaction [57] in two momentum regions as described in the text. The SM prediction was taken from [5] and scaled to the two pion momentum regions using the SM spectral shape for  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$ . The 68% and 90% C.L. intervals for the double ratio, described in the text, are also given.

Momentum range (MeV/c)	SM prediction	Interaction		
		SM	Scalar	Tensor
[130, 205]	$0.49 \pm 0.04$	$2.91^{+4.02}_{-1.79}$	$0.59^{+0.59}_{-0.35}$	$0.49^{+0.45}_{-0.31}$
[205, 227]	$0.28 \pm 0.02$	$0.49^{+0.45}_{-0.29}$	$3.50^{+4.68}_{-2.10}$	$3.10^{+4.23}_{-1.87}$
Double ratio	68% C.L.	(0.56,6.15)	(0.29,3.32)	(0.08,0.88)
	90% C.L.	(0.24,17.6)	(0.13,9.55)	(0.04,2.66)

acceptance assessed by each analysis. The probability that all seven events were due to background only (background and SM signal) was estimated to be 0.001 (0.073).

The  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  branching ratios for each of two pion momentum regions are given in Table XI along with the SM predictions. The combined E787 and E949  $\pi \nu \bar{\nu}(2)$  [ $\pi \nu \bar{\nu}(1)$ ] data were used for the branching ratio in the [130, 205] ([205, 227]) MeV/c region. The limits of the two momentum regions were determined by the requirements on the reconstructed pion region, the detector resolution, and the desire to have contiguous, nonoverlapping regions. The boundary between the two regions of 205 MeV/c was determined by the lower and upper limits on the reconstructed  $\pi^+$  momentum that were set to be approximately 2.5 standard deviations from the nominal  $K_{\pi 2}$  momentum for the  $\pi \nu \bar{\nu}(1)$  and  $\pi \nu \bar{\nu}(2)$  analyses, respectively. The lower limit of 130 MeV/c was determined by the  $\pi \nu \bar{\nu}(2)$  requirement on the reconstructed pion momentum. The upper limit of 227 MeV/c is the kinematic limit for the  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  decay.

The 90% C.L. upper limit  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) < 3.35 \times 10^{-10}$  was also determined and can be used to calculate a model-independent upper limit of  $14.6 \times 10^{-10}$  on the  $CP$ -violating process  $K_L^0 \rightarrow \pi^0 \nu \bar{\nu}$  [58]. This limit is substantially smaller than the current experimental limit of  $\mathcal{B}(K_L^0 \rightarrow \pi^0 \nu \bar{\nu}) < 670 \times 10^{-10}$  [59].

### C. Alternative model interpretations

The combined results of the E787 and E949 experiments can also be interpreted assuming a scalar or tensor interaction. The spectra are compared with the SM spectrum in Fig. 17. Using the same treatment of the data as for the standard model interpretation, the branching ratios for the scalar and tensor spectra alone were  $\mathcal{B}_{\text{sc}}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) = (9.9^{+8.5}_{-4.2}) \times 10^{-10}$  and  $\mathcal{B}_{\text{te}}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) = (4.9^{+3.9}_{-2.4}) \times 10^{-10}$ , respectively, or  $\mathcal{B}_{\text{sc}}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) < 21 \times 10^{-10}$  and  $\mathcal{B}_{\text{te}}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) < 10 \times 10^{-10}$  at 90% C.L.

The consistency of the distribution of the observed events with the shape of the SM, scalar, or tensor spectrum was evaluated using the double ratio

$$\text{DR} \equiv \frac{\mathcal{B}(130, 205)}{\mathcal{F}(130, 205)} \bigg/ \frac{\mathcal{B}(205, 227)}{\mathcal{F}(205, 227)} \quad (18)$$

where  $\mathcal{B}(P_1, P_2)$  is the branching ratio and  $\mathcal{F}(P_1, P_2)$  is the fraction of phase space in the momentum range  $(P_1, P_2)$  MeV/c. The ratio  $\mathcal{F}(205, 227)/\mathcal{F}(130, 250)$  is 0.084, 0.014, and 0.59 for the scalar, tensor, and standard model spectra, respectively. If the distribution of observed events were consistent with the shape of the assumed spectrum, then the double ratio would be unity. The 68% and 90% C.L. intervals of the DR and the branching ratios are given in Table XI.

The data have also been interpreted in the two-body decay model,  $K^+ \rightarrow \pi^+ X$ , where  $X$  is a massive noninteracting particle, either stable or unstable. The 90% C.L. upper limit on the branching ratio as a function of the mass of  $X$  is shown in Fig. 18. For the case of an unstable  $X$ , the decay of  $X$  was assumed to be detected and vetoed with 100% efficiency if  $X$  decayed within the outer radius of the

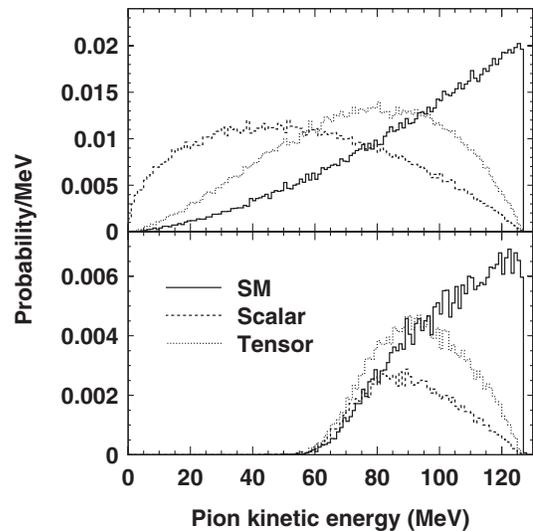

FIG. 17. (Top panel) The generated  $\pi^+$  kinetic energy spectrum for SM (solid line), scalar (dashed line), and tensor (dotted line) interactions. (Bottom panel) The distributions for events passing the  $\pi \nu \bar{\nu}(1 + 2)$  trigger.

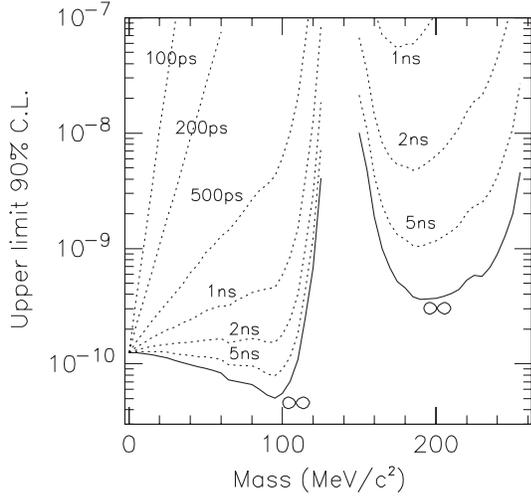

FIG. 18. The solid lines represent the 90% C.L. upper limit on  $\mathcal{B}(K^+ \rightarrow \pi^+ X)$  as a function of the mass of  $X$  assuming  $X$  is stable. The dashed lines represent the 90% C.L. for  $X$  with the indicated lifetimes as described in the text.

BV. The E949 limit of  $\mathcal{B}(\pi^0 \rightarrow \nu \bar{\nu}) < 2.7 \times 10^{-7}$  at 90% C.L. [60] can be combined with the world average value of  $\mathcal{B}(K^+ \rightarrow \pi^+ \pi^0)$  [24] to set a 90% C.L. limit of  $\mathcal{B}(K^+ \rightarrow \pi^+ X) < 5.6 \times 10^{-8}$  for  $M_X = M_{\pi^0}$  with  $X$  stable.

The limit in Fig. 18 can also be interpreted as a limit on the product of branching ratios  $\mathcal{B}(K^+ \rightarrow \pi^+ P^0) \times \mathcal{B}(P^0 \rightarrow \nu \bar{\nu})$  for a hypothetical, short-lived particle  $P^0$ . The HyperCP Collaboration observed three events consistent with  $\Sigma^+ \rightarrow p P^0$  with  $P^0 \rightarrow \mu^+ \mu^-$  having a mass  $M(P^0) = 214.3 \pm 0.5 \text{ MeV}/c^2$  [61]. A mass of  $214.3 \text{ MeV}/c^2$  would correspond to a recoiling  $\pi^+$  momentum, range, and energy of  $170.1 \text{ MeV}/c$ ,  $19.5 \text{ cm}$ , and  $80.5 \text{ MeV}$ , respectively, in a two-body  $K^+$  decay. Of the four events in the  $\pi \nu \bar{\nu}(2)$  region observed in E787 [45] and E949, the closest was the present candidate A that differed from the expected  $\pi^+$  momentum, range, and energy by 3.7, 2.4, and 1.5 standard deviations, respectively.

## V. CONCLUSION

### A. Summary

The branching ratio of the decay  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  is precisely predicted in the standard model to be  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) = (0.85 \pm 0.07) \times 10^{-10}$  [5]. As the decay is a flavor-changing neutral current process and thus sensitive to new physics effects [6], it represents an opportunity to unambiguously probe for physics beyond the standard model.

The E787 and E949 experimental program at Brookhaven National Laboratory has demonstrated the feasibility of observation of the rare decay  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  using stopped kaons despite the challenging experimental signature. The analysis presented in this article has estab-

lished that backgrounds can be reduced to a reasonable level while maintaining signal acceptance to enable the  $\pi \nu \bar{\nu}(2)$  region to be a viable supplement to the  $\pi \nu \bar{\nu}(1)$  region [2] in the measurement of the  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  branching ratio. The branching ratio  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu}) = (1.73^{+1.15}_{-1.05}) \times 10^{-10}$  for the seven events observed by E787 and E949 is consistent with the SM expectation.

### B. Final comments

We briefly summarize some important issues that emerged from the E787 and E949 searches for  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  and the measurement of  $\mathcal{B}(K^+ \rightarrow \pi^+ \nu \bar{\nu})$  in a stopped  $K^+$  experiment:

- (i) *Importance of blind analysis.*—The analysis procedure of concealing or obscuring the contents of the signal region [33,62] is now well established and widespread in particle physics. The main benefit is to avoid or minimize bias in the selection criteria. This is particularly important for a rare process such as  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  with a poor experimental signature that requires many individual cuts.
- (ii) *Use of data to estimate background and acceptance.*—In conjunction with the blinding of the signal region, the division of the data into 1/3 and 2/3 samples and the use of two powerful independent cuts provides background estimates that take into account instrumental effects not present in simulation and provides sensitivity to background beyond that of the  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  sample as first noted in [33]. The bifurcation technique also permits examination of events that occur near the signal region to validate the background estimates and investigate unforeseen sources of background.
- (iii) *Unforeseen acceptance losses.*—In the E787 proposal [63], only the  $\pi \nu \bar{\nu}(1)$  analysis region was considered to be viable and the estimated acceptance was 1.5%. This can be compared to the E949  $\pi \nu \bar{\nu}(1)$  acceptance of 0.22% [2] and 0.14% for the present analysis (Sec. III D). Accidental activity reduced the acceptance factors associated with vetoing. Acceptance was also reduced due to the cuts to suppress background, particularly related to muons in the  $\pi \nu \bar{\nu}(1)$  region and pion scattering in the  $\pi \nu \bar{\nu}(2)$  region, that needed to be more stringent than anticipated as well as due to cuts to suppress beam-related background that were not considered in the proposal.
- (iv) *Importance of redundancy in detector systems.*—In E949 and its predecessor E787, since nearly every detector element participated in the veto function for dealing with additional particles, the loss of any element represented a reduction in background rejection and motivated the redundant use of ADCs, TDCs, and high-speed waveform digitizers (CCDs or TDs).

- (v) *Need for 4- $\pi$  sr photon veto coverage.*—The early  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  counter experiments showed the benefits of photon veto capability over the full 4- $\pi$  sr solid angle [27,28]. Each modification or upgrade of the original E787 experiment included photon veto enhancements. For example, E949 contained upgrades with respect to E787 that sought to further suppress the contribution of the  $K_{\pi 2}$  background to both the  $\pi \nu \bar{\nu}(1)$  and  $\pi \nu \bar{\nu}(2)$  analyses. The BVL improved the photon veto rejection in the barrel region by a factor of 2 and the AD increased the photon veto rejection for the  $\pi \nu \bar{\nu}(2)$  analysis by 2 (Sec. III B 7).

Extrapolating from the E787 and E949 experience, it would be possible to extend the stopped  $K^+$  experiment approach to yield orders of magnitude more observed  $K^+ \rightarrow \pi^+ \nu \bar{\nu}$  decays [64]. As indicated above, the high rate of kaon interactions at 710 MeV/ $c$  resulted in reduced acceptance due to accidental spoiling of good events and increased backgrounds requiring highly restrictive cuts. If a higher primary proton beam intensity were available (with a high duty factor), lower momentum kaons, e.g. 450 MeV/ $c$ , would result in a much higher stopping fraction and reduced interactions which cause accidentals. To take advantage of this effect, a shorter particle-separated beam line (e.g. 13 m compared to the present 19 m), would be necessary to reduce attenuation of the kaon beam due to decay. Other improvements which would result in increased acceptance might involve use of a higher magnetic field (1 T  $\rightarrow$  3 T) allowing a more compact detector with

improved momentum resolution, finer segmentation of the range stack, a more hermetic, thicker fully active veto detector (e.g. crystals or liquid xenon), and an improved target.

## ACKNOWLEDGMENTS

We gratefully acknowledge the support and efforts of the BNL Collider-Accelerator Department for the high quality  $K^+$  beam delivered. We also recognize the substantial contributions made by the participants of E787 without which this work would not have been feasible, as well as the excellent technical and engineering support provided by all collaborating institutions including P. Bichoneau, R. Bula, M. Burke, M. Constable, H. Coombes, J. Cracco, A. Daviel, H. Diaz, C. Donahue, E. Garber, C. Lim, A. Mango, G. Munoz, H. Ratzke, H. Sauter, W. Smith, E. Stein, and A. Stillman. This research was supported in part by the U.S. Department of Energy, the Ministry of Education, Culture, Sports, Science and Technology of Japan through the Japan-U.S. Cooperative Research Program in High Energy Physics and under Grant-in-Aids for Scientific Research, the Natural Sciences and Engineering Research Council and the National Research Council of Canada, the Russian Federation State Scientific Center Institute for High Energy Physics, and the Ministry of Science and Education of the Russian Federation. S. Chen was also supported by the Program for New Century Excellent Talents in University from the Chinese Ministry of Education.
